All these outcomes are elucidated within the framework of Sullivan's interpersonal theory. The various solutions to acute psychotic reactions are seen as attempts to avoid, or to set up new interpersonal relationships, and the behavior of both the neurotic and the psychotic patient is made comprehensible by viewing it in interpersonal terms. The neurotic, by his substitutive processes, and the psychotic, through his reconstructive processes, attempt to achieve security and to avoid anxiety by relating to others from the vantage point of the neurotic or psychotic adjustments. The various categories of schizophrenia which are traditionally described as separate disorders were viewed by Sullivan as attempts at solu-

tion of the catatonic reaction. In his view, they all constitute restitutive processes rather than nosological categories.

Sullivan developed a psychological explanation for the etiology of schizophrenic disorder, and brought it directly into the nexus of personality theory by demonstrating that schizophrenic processes were never very far from the normal processes in living. In contrast to the prevailing theories regarding the etiology of schizophrenia, which were either of an organic, constitutional, or hereditary nature, Sullivan demonstrated that schizophrenia can develop as a direct outgrowth of psychological issues and that it could occur in any individual. Schizophrenia, which he differentiated from dementia praecox, is a personality distortion which grows out of a complicated and warped interpersonal history. He documented this notion in a series of fascinating case histories in which he might relate a particular delusional development, for example, to a series of interpersonal complications. The anxiety which resulted stimulated defensive operations designed to cope with these pressures. Thus, by demonstrating the origins of schizophrenia in the distortions of personality development, he stimulated the hope of a possible therapeutic resolution of this disorder through an unraveling of the history of its development.

Sullivan's concepts of neurosis and psychosis enabled the therapist to develop skills in dealing with schizophrenic illness through psychological techniques. Frieda Fromm-Reichmann and others have made notable contributions to psychiatry by applying Sullivan's concepts to the treatment of schizophrenia.

Treatment Techniques

Sullivan's views on therapy were a direct outgrowth of his conviction that psychiatry is the study of interpersonal processes, in which the psychiatrist functions as participant-observer. Since his concept of pathology is intimately tied to the self-system which develops out of the need to minimize anxiety, the focus in therapy is on anxiety and the interpersonal context in which it occurs. Sullivan viewed therapy as a succession of psychiatric interviews in which the psychiatrist is a participant in the exploratory process and an observer of trends in the patient which the patient's defensive patterns prevent him from noticing. The focus in therapy is on discovering how the patient came to be the kind of person he is, with his defenses and insecurities which have produced complications and difficulties in living.

Sullivan felt that the manner in which this could be pursued most effectively was through the investigation of anxiety, which will permit patient and therapist to see what the patient's insecurities are and where they lie, how they became stimulated in life situations and what defenses the patient uses to deal with them. This is achieved by dealing with sit-

uations in the present which could lead to the recall of earlier experiences. In this way, one can discover what was dissociated and why the patient had to keep it out of awareness. One can then assist the patient to permit the dissociated feelings or attitudes to come into awareness, thereby obviating the need for substitutive devices (neuroses) or disintegrative processes (psychoses). Briefly stated, this is Sullivan's philosophy of therapy.

He introduced a large number of parameters into the classical therapeutic technique. While he recognized the value of free association, dream analysis, and other symbolic reconstructions, his main emphasis was on the communicative process and what it could reveal regarding the patient's response to anxiety. The genetic reconstruction of the symptom took second place to data of recent origin, which were less prone to distortion. The use of the couch or the frequency of visits depended upon the needs of the particular patient, specifically, his dependency, financial status, degree of incapacity, etc., rather than on predetermined rules of procedure.

Sullivan believed that the process of therapy required the active participation of the therapist; therefore, anonymity was not considered a virtue. His view of transference phenomena differed from Freud's, and he developed the concept of parataxic distortion instead. With this concept he extended the notion of transference to include the multitude of distortions which develop out of parataxic interpretations of one's experience, not only with one's parents but also with other people such as teachers, friends, colleagues, etc. Because of the active role played by the therapist, counter-transference becomes an important technique in the therapeutic process. The use of dreams, free association, and other symbolic interpretations play a major role, as they do in classical psychoanalytic treatment. However, Sullivan insisted that such activities be pointed and directed at some particular question being explored at the moment and not used in an open-ended, unstructured inquiry. Values are part of the therapeutic process, to the extent that the therapist's feeling and attitudes could not and should not be kept out of the process. Such issues, however, need to be clearly understood and should always be used in the interest of enhancing the therapeutic process. Sullivan himself was a gifted, highly competent therapist who made great use of sarcasm and humor and demonstrated the value of such maneuvers in accelerating therapy.

The following is an abbreviated description of the treatment of a case of obsessional neurosis which demonstrates the main outlines of Sullivan's therapeutic technique.

The patient was a 24-year-old man who had spastic colitis and recurrent anxiety attacks. He was a bright, competent individual who insisted on immediate rewards and acknowledgement for skills he felt he possessed, but had not yet demonstrated. He was intensely anxious about every piece of

work he did and fearful of criticism. He expected his performances to be perfect. He could admit to no deficiency or error and needed to feel omniscient and omnipotent. His rituals were attempts to guarantee "superman" performances.

Treatment began by obtaining detailed data about his anxieties and the interpersonal relationships in which they occurred, with the aim of exploring some of his dissociated concerns about absolute security and invulnerability. His substitutive devices and rationalized explanations were exposed and he was able to see the patterns he used in trying to avoid anxiety. His verbal and gestural communications tended to obfuscate and confuse the relevant issues in his disorder, while his free associations tended to ramble and to be trivial. Active interference was required to bring him back to the point, in order to explore any issue at length. To help him recognize what his obsessional patterns were attempting to do, there was a constant necessity to focus on recent data; otherwise his obsessive doubts would cloud any interpretation in order to reduce its effectiveness. For example, often, his attempts to recall early experiences were clearly related to his wish to avoid exploration of a recent anxiety attack. Direct confrontation and questioning, as well as intervention, were regularly required to keep his communications within manageable limits, lest the interviews become rambling and evasive, with typical obsessional attempts to avoid the significant issues.

The therapist's activities stirred up considerable reactions of anxiety, defensiveness, counterattack, etc., during the therapeutic hour, and revealed the patient's typical patterns of behavior. Interpretation of these reactions enabled the patient to see how his perceptions were distorted by his expectations and the extent to which they were influenced by his neurotic needs. In this way, abundant transference data were produced, and the counter-transference reactions of the therapist toward the patient's excesses enabled the patient to see how his behavior affected others. Because of his need to be right and beyond criticism, every interpretation was viewed as an attack, and the therapist needed to demonstrate the distortion by becoming personally involved in the issue instead of objectively pointing out the patient's distortion. Dreams and other symbolic material were dealt with only to the extent that they clarified immediate issues and had relevance to current data. Intellectual discussions and the introduction of psychiatric terms were strenuously avoided.

When some clarification of the patient's anxieties was achieved and an understanding of some of his efforts at certainty and "guaranteed living" was arrived at the patient was encouraged to test out new patterns of behavior. He received strong support in taking risks and abandoning obsessional security operations, without overidentifying with the results.

Thus, therapy takes on many aspects of a learning experience in which the discomforts of learning new responses must be minimized by support and encouragement. The reconstruction of the individual's functioning without the props of obsessional devices is a difficult and painful process, and the patient must be prepared to experience some anxieties and helped to bear them. Therapy does not continue indefinitely but is gradually abandoned as the individual's skill in achieving improved interpersonal relationships develops. Since one must avoid trying to achieve a total cure or complete reconstruction of the personality (which, in itself, would be an obsessional pattern), the patient must recognize that being human means having anxieties and being vulnerable and insecure at times.

The therapeutic process was, for Sullivan, not only

an exploratory process for uncovering repressed or dissociated material, but also a learning process in which the restructuring of new patterns must be assisted. There is no special emphasis on sex, other than its role in the patient's life, and the sexual development of the patient is significant only to the extent that it elucidates the growth of his interpersonal capacities. The schema of personality development that Sullivan proposed becomes useful in assessing the interpersonal thwarts and complications and in identifying the stage of development at which such difficulties began.

Sullivan felt that therapy could be terminated when the person's perceptions of himself and others were "consensually validated." This is another way of saying that when a patient's capacity to see himself is validated by the view others have of him and is free of substitutive devices, and when his self-respect is adequate to withstand any view of himself by others, he can be considered to have achieved sufficient maturity.

Sullivan made his greatest contributions in the therapy of the psychoses. His notions that the schizophrenic responses were adaptive and restitutive enabled the therapist to understand a great deal of the confused and symbolic communications of the patient. Psychotherapy became recognized as a possible method for reversing the disintegrative process and was widely used, despite Freud's belief that psychoanalysis could not be effective in the psychoses. Sullivan's technique required modification of the classical model, but it made major inroads in the therapy and comprehension of the psychoses.

Since Sullivan believed that schizophrenia, like all other forms of mental illness, was due to some distortion or deficit in the development of interpersonal relationships, essentially, his therapeutic approach was similar to that used in the neuroses. However, the modifications introduced took into account the difficulties in communication as well as the schizophrenic's problems in relating to other people. In dealing with the schizophrenic patient, Sullivan attempted to develop his trust and participation by sharing his fear and anguish. He was not interested only in the patient's verbalizations, but in his non-verbal behavior as well. And he focused throughout on comprehending the anxiety that pervaded the schizophrenic's functioning, and which required such extreme defenses.

He attempted to actively encourage and stimulate the patient's interest in the therapeutic process. To do this, he would freely interpret the symbolic verbalizations or gestures and mannerisms of the patient. He did not hesitate to offer help and guidance in order to stimulate confidence and trust in the process. The goal of therapy was to enable the patient to recognize the source of his anxiety and to overcome his defective patterns by learning to deal with them in a more adaptive way. He was often content to settle for so-

cial recoveries; that is, manipulating the patient's life so that he would be exposed to situations which were less demanding and anxiety-provoking. He felt sufficient respect for the schizophrenic dilemma to realize that the passage of time during the illness often permanently incapacitated the patient, in terms of his return to a full social existence.

Sullivan's techniques required that the therapist know intuitively what was happening inside the patient and that he achieve rapport with him at that level, instead of following some rigid requirement of psychological theory. He would encourage and countenance any maneuver that contributed to understanding the illness, as long as it did not aggravate the illness, arouse anxiety unnecessarily, or show disrespect for the patient. Eventually, he hoped to strengthen the patient's self-esteem so that situations or relationships which had previously stirred up anxiety would now be dealt with in a diminished state of tension.

Sullivan did not feel that any limitations had to be imposed on the therapeutic process because the patient was catatonic or uncommunicative or actively paranoid. Instead, he would adapt his communications to encourage the patient's participation by making provocative statements or by actively becoming involved in his illness.

Finally, Sullivan experimented with milieu therapy by providing personnel in the hospital wards who he felt had greater empathy for the schizophrenic patient. This project did not fulfill his expectations; it provided, nevertheless, a strong impetus for later interest in the effects of the environment of the hospital ward on the patient's illness.

7.4 ERICH FROMM

SIMON H. NAGLER, M.D.

Introduction

Erich Fromm studied psychology and sociology at the University of Heidelberg and subsequently received orthodox psychoanalytic training in Munich and at the famous Berlin Psychoanalytic Institute before he emigrated to the United States in 1933. However, although he has drawn liberally from classical psychoanalytic thought, his focus of interest has been the relationship between man and his society. Thus his theories reflect the orientation of the social scientist, rather than the classical psychoanalyst's concern with the individual, *per se*. Insofar as he has sought to elucidate the relationship between psychological functioning and social milieu, his basic formulations are closely associated with the dynamic cultural positions of Adler, Sullivan, and Horney. Within this frame of reference, Fromm has contributed important insights into individual psychodynamics and their relationship to historical and socioeconomic concepts, which have exerted a significant influence on the layman, as well as on psychoanalysts, psychologists, sociologists, and philosophers.

Fromm and Freud: Major differences. In general, Fromm has been critical of many of Freud's formulations which he considers either inadequate or misleading because of their overemphasis on certain developmental phenomena. However, the chief target of his criticism has been Freud's concept of the source and nature of psychic energy, i.e., his libido theory. As opposed to the view of classical psychoanalysis, Fromm believes that "the fundamental basis of character is not seen in various types of libido organization but in specific kinds of a person's relatedness to the world," in the action of acquiring things and relating to people. Fromm has also been critical of Freud's failure to devote sufficient attention to the analysis of the mature or genital character, and he has differed sharply with the position of classical psychoanalysis with respect to the significance of dreams. While Freud defined dreams as the expression of the individual's irrational aspects, Fromm assumes that the dream "can be the expression both of the lowest and most irrational and of the highest and most valuable functions of our minds." Finally, Fromm has emphasized his disagreement with Freud's concept of

self-love as selfishness. In contrast, Fromm believes that selfishness is actually the opposite of self-love, which is really self-affirmation, which, in turn, is the basis for the capacity to love others.

Fromm's Theory of Personality

Man and society. Fromm recognizes that man's behavior is motivated by his biological requirements. However, he contends that man's adaptation is not related solely to the satisfaction or frustration of his instinctual or libidinal needs. Rather, human motivation (and behavior) are culturally determined, and society generates new needs and problems which are superimposed upon man's instinctual needs and are as imperative as the instinctual demands of hunger, thirst, and sexuality, if not more so. To quote from *Escape from Freedom*, the first volume Fromm published in this country in 1941, given the presence of certain universal instincts, "Those drives which make for the differences in men's character, like love and hatred, the lust for power and the yearning for submission, the enjoyment of sensuous pleasure and the fear of it, are products of the social process," not a part of a fixed and biologically given human nature. Thus, Fromm believes that society has a creative as well as a suppressing function; that man's passions and anxieties are, for the most part, products of his culture; and that man himself is the most important creation and achievement of the human effort of history.

Man's quest for meaning. Fromm draws an extensive analogy between individual development and the history of mankind. Man's biological helplessness at birth is the prime cause of the emergence of his specifically human qualities, e.g., his subsequent awareness of himself as a separate entity; his ability to remember the past and to visualize the future; his capacity for conceptualization and symbolization; and, finally, his realization that death is inevitable. These qualities give rise, in turn, to certain existential dichotomies—an awareness of being one with nature, yet transcending it; the hope for immortality, on the one hand, and the knowledge that death is inevitable, on the other. The human condition drives man to resolve these incompatibilities. Religion, with its promise of an eternal life, represents one such attempt at resolution. There are also historical dichotomies, such as that of abundance versus scarcity. However, these may be resolved through human wisdom and effort.

Above all, man differs from other animals because he has become separated from nature and other men; as a result he is overwhelmed by feelings of loneliness and isolation. He is compelled to relate significantly to self and others, to give his life meaning through the realization of his powers to reason and to love and of his capacity for productive activity. This provides the necessary frame of reference which will enable him to answer the questions of what he is and how he can best implement his search for meaning and belonging. This

human need for meaning and belonging is the key concept in Fromm's theory.

Separation and individuation. Just as man's history begins with his awareness that he is separate from nature, so the growth of individuality begins with separation of the newborn from the mother; separation occurs first through the physiological birth process and then through the individual's gradual psychological awareness of himself as an entity distinct from mother and other objects. Education, which necessarily involves frustration and prohibition, sharpens this awareness of separateness; once the primary ties of infancy have been broken, the child learns to use his own unique powers. And, gradually, he achieves greater physical, mental, and emotional integration, leading to the development of a structured self, guided by will and reason. Ideally, dependency is gradually surrendered.

On the other hand, the child's primary ties to his parents have given him a sense of security and belonging, which growth and individuation threaten to destroy. Confronted with an external world which appears strong and threatening, the growing child feels powerless and anxious. If his early experiences were unfavorable, in that he was deprived of respect, warmth, and affection, and if he failed to achieve confidence in his capacities as a result, the child will find the problems of individuation and isolation difficult, if not actually agonizing and insoluble. Generally, there is a lag between individuation and the development of a sense of security which is based on confidence in one's own capacities (rather than the omnipotence of one's parents). During this period the individual whose early environment was "unhealthy" may find his impotence and isolation intolerable; he may then seek to surrender his individuality and re-establish his dependency through one of several mechanisms of escape. These mechanisms, which include specific forms of neurosis, i.e., masochism, sadism, destructiveness, and automaton conformity, are discussed in further detail below, as pathological phenomena.

Theories of personality development. Fromm's theories of personality development are in harmony with his hypothesis that man relates to his world, either through acquiring and assimilating things ("assimilation") or by relating to people and to himself ("socialization"). He can take things or produce them himself, to satisfy his needs. But he must also associate with others in work, play, and sexual activities. Complete isolation is incompatible with sanity. The specific way in which the individual relates, that is, whether love or hate is predominant, competition or cooperation, freedom or oppression, is an expression of his personality or character.

Socialization may take one of five forms or orientations, which correspond to five types of assimilation. Socialization orientations include masochism, sadism, destructiveness, automaton conformity, and love. And

these are correlated with the orientations of assimilation which emerge as the receptive, exploitative, hoarding, marketing, and productive characters. Thus, for example, the receptive character is a masochistic person. These classifications are ideal constructs. In reality, human personalities are mixtures of these orientations, although one is usually predominant.

Temperament, as the mode of reaction to experience, is constitutional. As such, it influences the character of the activity in the several personality types. For example, the productive or loving personality with a choleric or irritable temperament will react vigorously to love; on the other hand, the sadistic person with this temperament will react vigorously to submissiveness in another. In this sense, personality, through which energy directed outward to the world is channeled, is the counterpart of the instinctual mechanism of the animal.

The family, the psychic agent of society, forms the child's character by compelling him to become a person who wants to do what is required of him as an effective member of society. Thus the core of personality is the "social character," on which the individual orientations are then superimposed. The reason why certain social character patterns predominate, rather than others, is a sociological problem. In any event, the social and individual character orientations are the end zones of a continuum which ranges from the conventionally patterned to the most idiosyncratic individual, as described below.

The receptive character. The receptive character, whose socialization orientation is basically masochistic, believes that his needs must be fulfilled by an external source, not through his own efforts. In fact, he feels inadequate and helpless. Therefore, he seeks a magic helper and becomes anxious when his "supply line" is threatened. Feudal societies fostered this orientation, which corresponds to the Freudian oral-passive type.

The exploitative character. This basically sadistic character, which corresponds to the Freudian oral-aggressive personality, attempts to seize what he requires from others, including things, ideas, friends, or mates. He is hostile, manipulative, envious, and cynical. Sociologically, he resembles the feudal robber barons and the "adventure capitalists" of the 19th century.

The hoarding character. Like the Freudian anal personality, the security of the hoarding character derives from his hoarding and saving activities. Spending arouses anxiety. Love is possession. He is orderly and pedantic, but generally sterile. Thus mastery is achieved through order and remoteness. Sociologically, this type corresponds to the bourgeois, Calvinistic-Puritan personality which was a product of the period of transition from feudalism to capitalism.

The marketing character. The marketing character, a product of modern society, is the automaton conformist. In this nonproductive orientation, indi-

vidual qualities have no intrinsic value. Personality is a commodity for sale; and there are fashions in personality just as there are in other commodities. Moreover, as might be expected, there is no genuineness or stability in human relationships. The classic example is the mythical character of Peer Gynt, who tries to find himself beneath layers of superficial values, only to find that he has no inner core of truth.

The productive character. This is the only productive orientation in Fromm's schema, and thus far it has not characterized society at any stage of its historical development, although Fromm has sufficient faith in humanity to believe that man will ultimately have the courage "to be himself and to be for himself." The criteria of productivity are the ability to reason independently and the ability to love. Love is a human capacity, but difficult to realize. As an expression of productiveness, genuine love implies care, respect, responsibility, and knowledge. The ability to love is acquired through loving specific individuals, such as members of one's family. Love for self is not incompatible with love for others; rather, the two are interdependent. Modern culture has produced individuals who cannot love themselves and who, therefore, cannot love others. The productive personality has many virtues; but these do not exceed appropriate limits. Thus, he is adaptable, but not unprincipled; he is active, but not exploitative. Finally, when productiveness is dominant, it tends to transform the nonproductive orientations in the personality. Under such circumstances, a tendency toward submission, for example, becomes devotion.

Authoritarianism is a basic concept of Fromm's thought. It is the most general mechanism of escape from the sense of isolation by seeking external powers, whether personal and direct, as that of a leader, or impersonal, as that of God. All forms of this mechanism serve to avoid personal responsibility and stultify the individual's creative productivity and growth. Basically, "the power to act creates a need to use this power and failure to use it results in dysfunction and unhappiness."

Fromm is averse to the anatomization of personality structure. Simply stated, he believes that only a spontaneous, integrated self can ensure the individual's successful relationship with his world. Therefore, since sex, for example, is only one of man's basic needs, it cannot function as a nuclear explanatory principle, nor can adequate sexual functioning be considered the sole prerequisite for happiness. "Happiness" is the result of free, productive activity which extends well beyond the limits of this single sphere of activity.

Theory of Psychopathology

Fromm has not dealt specifically with the differential diagnosis of mental disorders; he is concerned primarily with the role of modern society in the pathogenesis of such disorders. Accordingly, his main theo-

retical emphasis is on the neurotic mechanisms used by man to escape from the basic dichotomies in human existence. As mentioned earlier, these include masochism, sadism, destructiveness, automaton conformity, and neurosis.

Masochism. Masochism and sadism are usually conjoined in the sadomasochistic or authoritarian personality. The sadomasochistic person in whom masochism predominates feels inferior and insignificant, never experiencing the fulfillment and joy of freedom, which he fears. However, masochism does permit some sense of relatedness to others, despite the fact that such an individual remains weak, helpless, and dependent beneath his mask of love, loyalty, and devotion.

Sadism. Fromm delineates three types of sadistic behavior: (1) making others dependent by wielding unrestricted power over them; (2) exploiting and robbing others materially, intellectually, or emotionally; or (3) making others suffer. Actually, the sadist is not strong and independent, but weak and helpless. Unless he is able to dominate someone, he feels isolated and alone. Either trend (i.e., masochism or sadism) may predominate in the sadomasochistic personality. Anxiety arises when such a person is neither dominating nor submissive.

Destructiveness. The destructive person tries to destroy or eliminate another person or object who represents a potential basis for comparison or threat. Fromm formulated the attitude of this character type as follows: "I can escape the feeling of my own powerlessness in comparison with the world outside myself by destroying it." Such irrational destructiveness may masquerade as love, duty, or patriotism.

Automaton conformity. Some degree of conformity is required in any culture, of course. But in automaton conformity, the entire personality is dependent on the cultural pattern, and the individual becomes what others are and expect him to be. His fear of aloneness is overcome by thinking, feeling, and acting exactly like everyone else in his culture or group. A pseudo self is created.

Fromm sees these neurotic and characterological deformations as attempts to escape from the warping, alienating effects of a society that denies man's basic needs for relatedness, transcendence, rootedness, identity, and a stable frame of reference for the perception and comprehension of his world. It is the "sick" society that drives man into insanity, self-destruction, and antisocial behavior. The family communicates its traditional pathological mechanisms and social irrationalities to the child and reinforces these by communicating its feelings of hostility and anxiety.

Treated with hostility instead of warmth and respect, deprived of confidence in his own capacities, the child finds individuation difficult or impossible, and the escape devices described above are called into being.

Therapeutic Principles

Fromm has not developed a separate psychotherapeutic method. Instead, he has drawn freely upon other systems, particularly Freudian techniques. However, he differs from both the Freudian and the Jungian approaches in his use of dreams as a therapeutic tool. Specifically, Fromm believes that dreams reflect the rational, as well as the irrational aspects of personality. He has also introduced modifications in orthodox psychoanalytic technique with respect to the frequency of treatment sessions, use of the couch, sole reliance on free association; he has, in addition, advocated greater emphasis on current life situations. Finally, Fromm contends that the therapist must play a more active role in treatment. This stems, in turn, from his belief that insight must derive from experience which has an affective quality if it is to be therapeutically effective, and that this insight will determine the outcome of man's innate struggle toward health. Above all, Fromm is concerned with the requirements for a sane society, as a matrix for the creation of the productive, fully human man. Ideally, this would be a humanistic, communitarian society in which man could relate to others creatively as an individual, rather than a conformist.

Current Perspectives

Erich Fromm has not created a separate school of psychoanalysis, although his ideas have been adopted by many psychotherapists. He was chairman of the faculty of the William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology in New York City for many years. At present, he holds the position of Professor at the National University of Mexico where he teaches psychiatry and psychoanalysis, is Director of Psychoanalytic Training, and exerts considerable influence. In addition, Fromm's appeal to the general public remains undiminished, and he spends several months each year in New York City, lecturing to lay and professional audiences.

7.5 SANDOR RADO

HOWARD DAVIDMAN, M.D.

Introduction

Definition. Adaptational psychodynamics is the term used to refer to a body of psychoanalytic theory originally formulated and systematized by Sandor Rado and widely disseminated among many generations of psychoanalytic students. Early in his career, Rado worked closely with Freud and achieved eminence as an outstanding classical theorist and educator. Gradually, in the course of his work, Rado became increasingly aware of the need to rebuild classical psychoanalytic theory to conform to the criteria of biological science and scientific methodology. The accumulated clinical observations of classical psychoanalysis have been preserved as the basis of the newer adaptational theory. However, the explanatory principles have been revised so that they may truly serve to clarify and elucidate the data to be organized and explained, and the theory has been restructured to provide hypotheses capable of validation and suggestive of new research. The theory of adaptational psychodynamics also attempts to provide a basis for transoperational correlation with other scientific disciplines. It has been described by Rado as the "introspectional branch of human biology." As such, it postulates a basic theory of the science of behavior of the total organism.

Orientation

Areas of emphasis. During the development of adaptational theory, classical psychoanalytic theory was subjected to meticulous examination and scientific criticism; a partial report of the conclusions drawn from this examination is presented in this section. In general, this review served to underscore the importance of literate and detailed descriptions of clinical observations. It often seemed that the more abstract and poetic the theory, the more removed it became from the clinical data from which it supposedly derived. Extensive descriptions of clinical observations comprise the basic data which must then be organized and clarified through theory formation.

Review also pointed up the need for the precise and explicit definition of all technical terms. It was felt that deficiencies in definition and description in the body of classical clinical and theoretical psychoanalytic theory, as reflected in its literature and teaching, had assumed serious proportions. The attempt to preserve outworn theory by increasing patchwork on the libido theory, by refining the definition of energy sources, and by postulating subtler cathexes on

subtler structures had led to scholastic dogmatisms rather than recognizable scientific statements.

Finally, adaptational psychodynamics strives to establish a correlation between psychological knowledge, gained through introspection, and the physiological findings derived from the inspective sciences. Freud believed that psychological functioning would ultimately be explained in organic terms but felt that the knowledge of neurophysiology then available was inadequate for this task. Rado believes that the introspectional and inspectional aspects of brain activity must be correlated by cross-interpretation and that the theory must be open to new knowledge which would continually increase the degree of correspondence.

Psychoanalysis as science. Orthodox psychoanalytic theories served the proper function of scientific theory at the initial stages in the development of the science. More specifically, they represented a first attempt to organize overwhelming, chaotic, and novel psychic data which had been elicited through the use of a revolutionary technique which was misnamed "free association." The theories which interpreted these data provoked new questions and stimulated new areas of research and thereby fulfilled the basic function of all scientific theory.

Thus, subsequent direct studies of the behavior of the child were inspired by Freud's retrospectively based hypotheses concerning the emotional life of children and the stages of psychosexual development. The scientific value of classical psychoanalytic theory is also evident in the stimulus Freud's anthropological speculations provided for modern systematic comparative anthropological research into personality development in diverse cultures with varying child-rearing practices. Nor is the significance of this contribution diminished by the fact that Freud's original hypotheses which drew on the meager cultural knowledge then available and those that resulted from his misapplication of Haeckel's law of recapitulation ("ontogeny recapitulates phylogeny") to sociology were disproven later in the light of subsequent knowledge.

On the other hand, classical psychoanalytic theory includes constructs which are inadequate and misleading, such as those which postulate an innate normal progression of pleasure-seeking behavior through various phases (including a homosexual stage and a latency period) which are organized around the specific "erogenous zones." And Freud's dual instinct theory is not a scientific theory at all, since it does not permit testable study of clinical phenomena; nor can it be validated by any scientific method. Rather, it represents a philosophical abstract description of the origins of behavior which, according to the adaptational school, is remote from the real motives which govern behavior. Another example of differences with the adaptational viewpoint is Freud's conten-

tion that neuroses arise solely as a result of difficulties in the resolution of the Oedipus complex.

More precisely, Freud's original theory of mental functioning was built around his concepts concerning six elements considered essentially sound by the adaptational school: (1) motivation, (2) pleasure seeking and pain avoidance, (3) repression, (4) mental mechanisms, (5) mental apparatus, and (6) evolutionary and individual history. However, after 1905, Freud's tendency toward speculation increased, as evidenced by his arbitrary expansion of his sexual theory and his introduction of the animistic concept of "instinct." Thereafter, he persisted in the development of mystic animistic concepts, despite his own warning that the instincts were vague and mythological and that his tripartite model of the mind was not to be interpreted literally. Adaptational psychodynamics discards these hypotheses and procedures and reverts to the body of factual knowledge and sound mechanistic theory which were characteristic of Freud's early approach. Only through reorganization which will enable "transoperational correlation with the findings of science" can psychoanalytic theory achieve the goal Freud set for it.

Methodological principles. Adaptational psychodynamics treats the historic concern over the mind-body problem as a paradox resulting from the scientific observer's confusion over his own methodology. The human organism is viewed as an integral unit. The methods of studying the organisms will vary according to the functions to be studied; concomitantly, the type of information obtainable will be determined by the methods available for such investigation. Introspectional material, the product of the reporting function of the brain, is studied by means of a psychological tool such as psychoanalytic exploration. On the other hand, physiological brain functions and other functions of the body are studied by inspectional methods which use structured techniques to measure performance. The psychoanalyst's unique capacity for self-awareness and self-observation is the investigative tool in psychodynamic matters. The psychoanalyst may be a crude measuring rod, but he is the best there is. Confusion has resulted from misguided attempts to explain inspectional data by introspectional means, and vice versa. There is no validity to the charge that the study of psychodynamic matters cannot conform to the methods of science. Any set of data can be studied scientifically, if the appropriate method or instrument is used. Statistical methods may satisfy a primitive thirst for exactitude, but when statistical approaches are misapplied, they can only provide an illusion of knowledge. An introspectional or psychological method is the appropriate one for measuring the cerebral mechanisms of motivation and control, and the complex findings are best expressed by the skillful use of language.

Personality Theory

Although Rado recognized Freud's enormous contributions to science, he did not consider Freud's theories immutable. Rather, he believed that the future progress of psychoanalysis as a science depended on the further modification and clarification of classical theory. To this end, he used simpler and less abstract explanations, removed undefined terms and obscure references, and reorganized the material in simple hierarchical terms.

Behavior as a teleological phenomenon. "Adaptation" was postulated as a core concept to emphasize Rado's evolutionary biological orientation. Thus the theoretical frame of reference conforms to the dictum "adjust or perish," which must be obeyed by both the individual and the species. The emphasis on adaptation has served, in turn, to refocus attention on the continuing influence on development of mutually reinforcing interactions of ever increasing complexity between the child and the people and things in his environment. In his later theoretical formulations, Freud minimized this aspect of development and emphasized the role of constitutionally determined internal forces which seemed to operate autonomously.

Adaptational theory conceptualizes and evaluates behavior in terms of its utilitarian and survival functions. Thus, pleasure seeking is seen as a means to the adaptive end of fulfilling the organism's needs in biological interaction with its environment; therefore, it also serves to insure the preservation of the individual and the species. Pleasure is not an end in itself. It follows, then, that adaptational psychodynamics is concerned with goal-directed behavior. Behavior is conceived of as a means to an end; it is evaluated in terms of its goal-finding and goal achievement functions, which are designed to reduce or eliminate equilibrium-disturbing tensions that arise within the organism and to establish a new equilibrium. The observer interprets the adaptive value of behavior in terms of his evaluation of its evolutionary or survival value. Our psychology has adopted the teleological orientation which characterizes modern biology and physiology.

Motivation and emotion. In his early formulations Freud emphasized, as we do today, that behavior must be studied in its motivational context if it is to be understood. However, Freud departed from this fundamental insight in his later theoretical constructs, specifically, his instinct theory, his theory of constitutional bisexuality, and his tripartite model of the human mind. In so doing, he replaced mechanistic concepts with animistic notions which failed to explain behavior in terms of its motivational context. Adaptational psychodynamics does not employ concepts which describe imaginary energy (e.g., "libido") or its cathexis on imaginary structures to explain motivation. Instead, it identifies the forces which motivate behavior as the emotions themselves. Thus,

the emotions are defined as the integrating forces which mobilize the organism to take action which is designed to fulfill its needs.

The only human energy that science recognizes is the conventional metabolic energy studied in physiology and biochemistry, measurable by inspective, rather than introspective, methods. This is actually the energy underlying brain activity. Psychodynamic phenomena are observed, measured, and explained through the human capacities of introspection, language, and thought. Freud discovered an appropriate method to enable searching scientific exploration of introspectional material, and called it "free association." However, Rado uses a descriptive term for it, "communicated deep introspection." The relationship of mind to brain activity is one of congruence, not identity. To quote Rado, "Consciousness is the awareness of the running report produced as its inward expression by the underlying nervous activity of the brain. The latter may be called the *reporting process*, and consciousness, the *awareness process*. . . . The rest of the brain's activity is non-reporting (i.e., purely physiologic). Nevertheless, even this purely physiologic brain activity may, through proper channels, influence the reporting process and correspondingly, the awareness process." The extrapolation of introspectional language enables identification of nonreporting emotions, specifically, when the awareness process reveals a gap in motivational understanding and the context in which the gap appears enables the observer to draw the requisite inferences, that is, to describe nonreporting fear, rage, desire, etc. In summary, although this concept recognizes that brain physiology operates on a different level from the psychological concept of motivation, it nevertheless links behavior to brain activity. This dispenses with the obscure connotations of "the unconscious."

Concept of emotion. Freud's instinct theory, and particularly his libido theory, obscured the primary role of emotions in human life; instead, they were described as secondary derivatives or epiphenomena. In contrast, adaptational psychodynamics places the study of emotions in the foreground as the clearly observable mobilizing forces of behavior, on a psychological level, and describes their action in introspectional terms. Following the physiological concepts outlined by Cannon, the emotions are divided into two classes. The emergency emotions, such as fear, rage, shame, guilty fear, guilty rage, are based on present pain or the anticipation of pain. The second class, the welfare emotions, such as desire, joy, affection, love, and pride, reflect present pleasure or the anticipation of pleasure. The welfare emotions stem from pleasantly toned forces of attraction and gratifying interaction with a mothering person.

The emergency emotions provide the organism with an "emergency control," and protect it from danger and anticipated danger. For example, fear and

rage protect the organism by mobilizing it for fight or flight in the face of tangible or rationally perceived danger. If the danger cannot be dealt with and the organism freed from continued fear and threat of damage, the organism will be flooded with inappropriate and excessive emergency emotions which no longer perform a protective function, but are damaging in themselves. Examples of the effects of "emergency dyscontrol" are cases of acute war neurosis or acute neurotic failure. If this reaction cannot be mastered by conscious thought, there follow nonreporting thought, repression, and the other automatic mechanisms of repair, e.g., hysteric, obsessive, phobic, and other syndromes. These syndromes are classified diagnostically according to the psychodynamic mechanisms involved. They serve to free the organism, partially, from the painful excess of stimulation produced by excessive insoluble fear. The organism is then able to function once again, although the functioning will, of course, be constricted.

Central integrative apparatus. Adaptational psychodynamics hypothesizes a "central integrative apparatus" which is described in terms of hierarchical levels of central integration and control of the organism's motivations and behavior. This hierarchically organized structure reflects the evolutionary history of the species and is presented schematically as consisting of four levels: (1) hedonic self-regulation (the most primitive), (2) preverbal brute emotion, (3) emotional thought, and (4) unemotional thought.

Hedonic self-regulation. The level of hedonic self-regulation is achieved by the human fetus or the semicomatose adult. In terms of evolution, it corresponds to the integrative functioning of the protozoa. At this level, the organism's capacity for foresight, its ability to anticipate the future, is minimal. It simply moves toward objects that fulfill its need and away from noxious stimuli. Nevertheless, there is evidence of discrimination, of awareness of the presence of needed supplies and of other conditions favorable to survival, and, conversely, of the presence of danger. Thus, with respect to evolution, hedonic self-regulation is of obvious survival value. Contact receptors and rudimentary nervous nets are used at the hedonic level. Tension, pleasure-pain, attraction-repulsion mechanisms, and reference to past experience in terms of feeling residues are present. Tropisms and simple conditioned behavior are also manifested by the organism at this level. These forces enable the organism to obtain optimal conditions of food, oxygen, light, temperature, water, and to integrate motor behavior which is designed to permit it to take and retain needed objects and avoid damaging ones. Finally, hedonic self-regulation is the primitive basis of pain-pleasure physiology.

Pain and pleasure govern the operative patterns of the organism at higher levels of integration as well.

For instance, the ability to construct abstract mathematical formulas is also governed by sophisticated application of the pain-pleasure principle. Mathematical thinking produces rewards and punishments, successes and failures, and evokes feelings of pride or provokes a loss of self-esteem, despite the fact that it involves unemotional thought.

In fact, mechanisms for the avoidance of painful stimulation exist at all levels of the psychodynamic cerebral system, and in the integration of peripheral (somatic) levels, as well. Rado refers to these mechanisms generically as "riddance mechanisms," and he has emphasized their presence in all animal design, and at each level of organismic integration. On the physiological level, the riddance mechanisms include such reflexes as vomiting, scratching, lacrimation, sneezing, coughing, etc.; on the psychological level, the primary riddance mechanism is repression. Repression is the automatic riddance of painful thought and emotion through exclusion of the painful processes from awareness.

Preverbal brute emotion. The level of preverbal brute emotion corresponds to metazoan evolution. The emergency emotions of fear and rage appear at this higher level of organization and perform the same adaptive function as pain. The evolution of distance receptors and the increasing specialization of the head end of the organism and of nervous system control at the head end must have preceded the appearance of the emergency emotions. There is "sensory exploration of the shell of the immediate future," speedier motility, evidence of predacity, and an extended period of care of the young. There is increased delay of motor reaction to stimuli as the brain develops at the head as the "manager of muscle," in response to its increased capacity to receive signals and, as a result, greater effectiveness and discrimination of action. The welfare emotions also appear as mobilizers of the organism to action. The emotions are expressed in order to warn of impending danger or elicit cooperation. Thus, they serve as a communicative mechanism on the group level. The emotions are of evident survival value and have feeling tone and voluntary and autonomic expression.

Emotional thought. At the emotional thought level, brute fear and rage are modified and take the form of apprehensive and angry thought. Language and thought processes have appeared, and there is exploration of present, past, and future experience. The cerebral cortex has become dominant. There is greater discrimination, diversity, and flexibility of motor performance. The basic emotions have become differentiable into shadings and compounds of derivative emotions. The learning process is highly developed, and the dependency period is extended. Regulation by reward and punishment is maternal at first and is then governed by society. Reasoning develops; symbols rather than things, are manipulated; thought is trial action and provides increased effi-

ciency. Yet, emotional thought is selective, not objective; it tends to be self-justifying and feeds the emotion from which it springs and by which it is controlled. Consciousness and self-awareness are present at this level.

Unemotional thought. The unemotional thought level is characterized by "rational" or "objective" thought. At the present stage of social evolution, there is continual struggle between rational and emotional thought for dominance in personal and in political life. Unemotional thought corresponds to the transcendence of intellect over emotions. This is achieved by intellectual mastery of the emotions; and in the process, intellectual activity becomes increasingly complex. Intellectual activity becomes an exploratory and mastery tool of increasing dependability, which can operate in relation to phenomena far outside the "shell of the immediate future." This level provides a fine adjustment of the equipment for survival: man's complex culture develops from its use, and his social survival now depends on its effectiveness.

Controlling unit: The action self. The controlling unit of the entire psychodynamic cerebral system is the "action self." Rado identified the action self as occupying an axial position in relation to the four hierarchical levels described above and as deriving from the central importance of the uniquely human capacity for conscious self-awareness. This self-awareness emerges from and is sustained by infantile proprioceptive sensations. The baby, perceiving his muscular activities, discovers himself as the one who acts. The psychological interaction between self-awareness and willed action is the psychodynamic expression of unfolding innate circuits of brain activity. On this foundation, the organism builds its systematic self-image, or action self. Combining kinesthetic with other sensory information, the organism learns to recognize itself as a cohesive, enduring being. The self-image is formed as the organism focuses attention on the equipment it uses to control its environment. Changing profoundly as it develops, the action self is originally filled with pleasure by its success in sucking and attributes limitless power to its willed actions; it pictures itself as omnipotent. This is termed the "primordial self." At this stage, the infant sees his parents as deputies who exercise his magic powers for him. The tested self develops from the primordial self as a result of continual defeat of this feeling of omnipotence in the face of realistic experience. The self then develops as a reliable, tested self, differing to various degrees from the desired self. This process involves delegatory and emulative identifications, the awareness of one's capacities, and the ability to change the longing for omnipotence into a desire for achievement in socially rewarding directions. These achievements then become a source of self-reward, or pride. Emotional self-approval, the function of the action self known as pride, rises and falls, depending on the

amount of pleasure the action self consumes. The action self is the supreme decision maker and controls activity at each of the four levels of the integrative apparatus.

Theory of conscience. The conscience develops as the preventive branch of emergency control and consists of self-restraining and self-prodding mechanisms which enable the action self to adapt to societal demands. It arises in the dependency situation at the level of emotional thought and enhances the organism's fitness for cooperation, first with mothering persons and then for increasing cultural cooperation. Conscience regulates conduct by self-punishment and self-reward. Cultural rules are transmitted to the child by parental regulations, which are enforced by reward and punishment. The child's reactive fear of punishment restrains forbidden activities. His obedience is rewarded by loving care, to which he responds with heightened pride. These mechanisms, automatized to varying degrees, continue into adulthood in the form of fear of social punishment, on the one hand, and rising pride in social recognition, on the other. Conscience proper derives from the child's belief that his parents are omniscient and his resultant fear of inescapable punishment. When this is automatized it becomes the fear of his own conscience, and this is the most differentiated and dependable mechanism of self-restraint humanity has achieved. Obedience to the "voice" of conscience elicits the self-reward of rising pride.

When temptation and defiant rage overrule the fear of detection and punishment, disobedience and efforts to escape detection follow. In submissive obedience, defiant rage is submerged by fear. With growth and loving identification facilitated by the influence of rewards misbehavior causes guilty fear, which acts as a warning signal that loving care is threatened and must be restored. Thus, the complex emotion of guilty fear consists of self-criticism, the awareness of wrongdoing, and the fear of inescapable punishment, intensified by dependence on loving care, together with repression and retroflexion of defiant rage on the self. When temptation and defiant rage overrule the fear of conscience, disobedience causes guilty fear and falling self-respect or pride. Repair is effected through expiatory behavior taught in childhood and designed to elicit self-forgiveness—modeled on parental and social forgiveness. Self-respect is thereby elevated again. Atonement maneuvers aim at restoring self-respect and are modeled on the earlier restoration of parental care and social approval after repentance, at a time when the child was in a state of dependence.

Theory of Psychopathology

The dynamics of depression are traced to the miscarried application of automatized conscience mechanisms to the repair of the results of serious failures in realistic living.

Depression. Important failures in realistic mastery

cause excess fear and impotent rage which may surpass resolution by the resources of intellectual activity. If fight or flight fails on all levels, hopelessness ensues. Then, on a regressed and inappropriate level, guilty fear and expiation offer the hope that by self-punishment and forgiveness, concomitant magic help can be coerced. Even when this proves illusory in reality, the hope does not die; rather, there is resort to further and angrier self-punishment to secure the desired end. In the face of realistic failure, this regression to dependent automatized angry expiatory proceedings is the miscarried repair that underlies the depressive reaction.

Homosexuality. In adaptational theory, sexual theory has been revised in the light of modern knowledge, since Freud's theory of constitutional bisexuality has been refuted by modern embryological and endocrinological knowledge. Nevertheless, Freud's theory persists in the theory and practice of many psychoanalysts, as evidenced in their search for "latent homosexuality." This orientation, when it persists, can be quite destructive; it confuses clinicians and causes despair to many patients who attempt to analyze a mythical constitutional latent homosexuality, in the magic hope that this will relieve their suffering which, in fact, is due to entirely different emotional motivations and failures of function.

Adaptational psychodynamics has reemphasized the essential heterosexuality of all mankind, based on reproductive anatomy and the institution of marriage, imprinted on the mind of the child early in his development. The fulfillment of the reproductive goal is dependent on childhood learning. Heterosexual function is often damaged by the impact of early parental threats; fears and rages may affect the assertive capacity of the individual, and the assertion of his sexual desires, in particular. The partially incapacitated child attempts to repair the damage as he matures, and one reparative device, among many others, is the attempt to reproduce heterosexual union in the absence of the frightening and forbidden organ of the other sex. Thus, he is able to avoid fear and guilt, as well as the fear of the humiliation of failure in sexual performance, and achieve orgasmic satisfaction nevertheless by means of an illusory or fantasized heterosexual mating between partners of the same sex. Simultaneously, dependent, hostile, and power-seeking motivations are prominent, and usually sexual love is only counterfeit. Frequently, as homosexual partners grow used to each other, physical sexual activity becomes increasingly rare. However, homosexuality can only denote behavior motivated by the desire to have orgasmic experiences with a partner of the same sex; it cannot serve as a label for all passivity and inhibition.

"Masochism." The concept of miscarried repair mechanisms to compensate for failures in the emergency function of the organism is used extensively in adaptational psychodynamics to explain a wide range

of psychopathological symptomatology. Thus, "masochistic" behavior is explained in terms of automatized obedience and submission to old parental threats of punishment before forbidden pleasurable goals can be experienced and achieved. This is self-punishment elicited by guilty fear, administered in advance of obtaining prohibited pleasures. Rado describes this as "pain-dependent behavior," which can be observed in all forms of disturbed pleasure functioning. This explanation is based on the desire for mastery, experience, and pleasure, despite inhibitory fear and guilt. According to adaptational theory, it cannot be attributed to death-seeking instincts, or sadistic or masochistic components of a sexual instinct.

Classification of behavior disorders. Ideally, the production of emergency emotions, such as fear, rage, guilty fear, and guilty rage, will lead to the realistic resolution of the threatening situations. However, where healthy resolution fails, there develops an overproduction of these emotions which then presents the organism with an additional threat from within with which it must cope. The overproduction of emergency emotions, termed "emergency dyscontrol," is the simplest form of behavior disorder; other clinical syndromes depart from this source and may be classified in a sequence of increasing complexity of their patterns of attempted self-repair. Rado's classification, as incorporated in his theory of adaptational psychodynamics, provides the following seven classes of behavior.

Emergency dyscontrol. Emergency dyscontrol includes the emotional outflow; the riddance through dreams; the phobic, the inhibitory, the repressive, and the hypochondriac patterns; and the gainful exploitation of illness.

Descending dyscontrol. Descending dyscontrol may be defined as autonomic discharge of repressed but overflowing emergency emotions into the various component systems—respiratory, circulatory, alimentary, endocrine, etc.—of the whole organism.

Sexual disorders. These include impairments and failures in standard performance; dependence on reparative patterns (e.g., organ replacement and organ avoidance; the criminal, dramatic, and hidden forms of sexual pain dependence; the formation of homosexual pairs); fire setting and shop-lifting as sexual equivalents.

Social overdependence. Social overdependence is characterized by the continuous search for an ersatz parent and the mechanisms of forced competition, avoidance of competition, and self-harming defiance.

Common maladaptation. This is a combination of sexual disorder and social overdependence.

The expressive pattern (expressive elaboration of common maladaptation). This pattern includes ostentatious self-presentation; dreamlike interludes; rudimentary pantomimes; disease copies and the expressive complication of incidental disease.

The obsessive pattern (obsessive elaboration of

common maladaptation). In this pattern are included broodings, rituals, and overt expression of temptations; tic and stammering as obsessive equivalents; bed wetting, nail biting, grinding of teeth in sleep, as precursors of the obsessive pattern.

The paranoid pattern (nondisintegrative elaboration of common maladaptation). This pattern is the hypochondriac, self-referential, persecutory, and grandiose stages of the Magnan sequence.

Theory of schizotypal organization. Adaptational psychodynamics recognizes that there is a qualitative difference between schizophrenia and the neuroses, in terms of organizational deviations which involve the entire organism. It also postulates that schizophrenia depends on a variable (but necessary) genetic predisposition, which is operative throughout the life of the schizophrenic individual. Thus, schizophrenia is not caused by "schizophrenogenic" mothers; rather, these mothers have been upset by the atypical reactions of their "schizotypal" babies. "Schizotype" is Rado's abbreviation of schizophrenic phenotype, and his theory holds that the genetic predisposition finds physiological and psychological expression in unique forms. When psychodynamically organized, the clinical data reveal difficulties traceable to a compound of inherited defect, faulty childhood experiences, and miscarried efforts of the individual to repair his deficiency and "stay afloat."

According to Rado, schizotypal "differentness" resides in two fundamental forms of damage. These are an integrative pleasure deficiency and a proprioceptive disorder. The diminished pleasure capacity weakens the motivation for every action of the integrative apparatus throughout life. Normal welfare emotions, which are essential for performance and growth toward enjoyable cooperation and love, are lacking. Consequently, the pleasure deficiency weakens the balance of emergency emotions, and fear and rage rise to an excessive and unmodulated strength. The coherence of the over-all control of the action self is disrupted by intense emotion, and self-confidence is undermined because the socially acceptable integration of behavior is so difficult to achieve. The enjoyment of all the complex tasks and relationships of adult life is weakened.

The proprioceptive disorder also damages the action self from the time of its early formation through awareness of willed action in early childhood and throughout life. These two sources of damage to the action self leave it brittle and prone to disintegrative breakdown characterized by thought disorder. The extent of these two defects varies from patient to patient, as do the genetic predisposition and the nature of the traumata of life experience. However, the consequences pervade every area of behavior. The following four processes of automatic repair are described as typical of the organism's attempts to compensate for the defective self.

Extreme overdependence. Extreme overdepend-

ence throughout life, together with an inability to give love and affection, is usually accompanied by responses of fear and rage to parental demands and gross obedience or gross defiance, with little in-between range of emotional shading. This dependent craving is resented, and the anger is aimed at those on whom the individual is forced to depend.

Scarcity economy of pleasure. A scarcity of sources of pleasure forces the individual to cling to every morsel of pleasure. Thus, any loss of small pleasure is experienced as a severe blow. However, a favored or routine pursuit may absorb the entire limited capacity for pleasure.

The use of intellect. Intellect is used to do the job ordinarily done automatically by pleasurable feeling. Unemotional thought is used to figure out how to live in the emotional world of other people, whose emotions are not shared by the individual. This attempt to imitate other people's pleasurable reactions may create the impression of oddness, unexpected humor, or creativity.

Greatly increased craving for magic. The preceding three reparative devices may sustain a workable adjustment, but this one miscarries because it defeats adaptation. It provides solace, the individual tends to rely on it, and it can eventuate in delusion.

The clinical outcome depends on the efficiency of the first three repair mechanisms, in relationship to the total adaptive resources of the organism. These include intellect, education, privileges of wealth and social position, opportunities, the establishment of achievable goals under the enlightened guidance of parents and psychiatrist, and the capacity for healthy repair. Adaptive failures tend to develop under the stresses of life and the conventional expectations for performance according to the patient's chronological age. As the individual becomes aware of his failures in adjustment, he is flooded with fear and experiences a severe loss of pride, and if he finds no acceptable way out, decompensation may ensue with acute schizophrenic panic. He may then resort to more regressed magical methods of repair that produce much of the overtly psychotic symptomatology.

Treatment Techniques

Rado's theory of treatment includes the goal of raising the level of the patient's psychological development by remedial reeducation, which transcends the removal of symptoms. To achieve this, it is important to trace the patient's history from the present back to the formative experiences of his early years. It is necessary to overcome the patient's fears and resentments in order to help him to communicate fully; the interpretation of the hidden meaning and motivating power of his emerging memories, ideas, and emotions will then prove more fruitful. Finally, to achieve the goal of reeducation, it is necessary to keep the patient's emotional relationship to the physician under control. These principles are in accordance with

Freud's concepts, which we recognize to be valid today.

However, Freud's theory of treatment eventually became dominated by the concept of transference, which had its origins in the mysterious force known as the repetition compulsion. Transference is a descriptive, rather than a motivational term. Moreover, the abstract power of transference and resistance obscured the motivations of the patient's behavior. The adult patient's childish love and hate of the psychoanalyst derives from the child's pursuit of emotional security in the interest of survival. Whenever he feels helpless, he reverts to the early adaptive pattern of infantile dependence. Under the continued stresses that have induced the adult patient to undertake treatment, he behaves toward the psychoanalyst with the invocatory mechanisms aimed at magic fulfillment which he learned under childhood stress. This behavior does not solve his problem but only creates new difficulties. For example, the classical technique tries to encourage development of a "positive" transference, which may be considered to consist of an overly dependent relationship with a distorted image of the therapist. Once the transference is achieved, the therapist is no longer seen realistically as another human being who is an expert in human relationships and who is to be consulted because he can help the patient to work out more effective ways to master his emotions and interpersonal relationships. The dependent and magically idealized view of the therapist may never be resolved in classical technique.

In contrast, the adaptational technique attempts from the start to work against the patient's search for a repetition of a dependent parental relationship. It attempts to prevent perceptive distortions of the psychoanalyst by which the patient strives to fulfill his magical hopes, and it presents the analyst in human proportions. It attempts to help the patient to achieve the most realistic level of integration of which he is capable and to help him to move to more integrated levels of functioning. Prolonged regression, which is inevitable in classical psychoanalysis, is considered to preclude achievement of these goals.

Rado emphasizes that the undoing of repressions is only a first step in treatment. Once inhibiting fears begin to be relieved, a positive program of emotional reeducation is undertaken, in order that the patient may become aware of his emotional capacities for pleasure, assertion, and competition in reality, and thereby learn the lessons he could not master while he was dominated by emergency emotions and inhibition. This is a reeducational process, which begins where classical psychoanalysis ends, with development of the welfare emotions while the patient is maintained on the self-reliant or aspiring level. This procedure builds pride based on realistic, successful performance in areas where the patient had failed previously and in new areas now open to the patient's curiosity and striving.

Adaptational psychotherapeutic technique avoids classifying patients according to specific methods of treatment. Its theory describes the therapeutic needs of all emotionally troubled patients; it does not recognize that certain people are not "eligible" for analysis. Treatment is designed to meet the needs of the patient after a detailed history taking, and an evaluation of his functioning capacities, the extent and nature of his inhibitions, and his capacity for change.

While elaborating his theory of treatment, Rado offers a deceptively simple and most helpful schema for describing psychotherapeutic methods based on the motivational and integrational level on which they are conducted. The schema obviates the futile argument over whether a treatment is psychoanalytic, based on such criteria as the frequency and duration of sessions, their total number, the posture of the patient, the material dealt with, etc. Meaningful treatment is based on the application of sound psychodynamic principles which serve as a guide to the psychotherapeutic needs of all patients.

The descriptive schema alluded to above charts the hierarchical order of the patient's designs for cooperation with the therapist. On the basis of the patient's capacity for cooperation, on self-reliant or aspiring levels of function, reconstructive therapy can be done. Patients who employ mainly methods of cooperation based on a search for a parent figure or for magic and who are incapable of a shift to more integrated and mature levels of treatment behavior must be cared for properly by methods integrated on levels suited to them. Thus, there is room in the armamentarium of adaptational psychodynamics for reparative psychotherapy, hypnotherapy, pharmacotherapy, and other techniques which rely for their effectiveness on the forces inherent in these patients' search for magic and for parent figures. The appropriate levels of treatment for each patient must be diagnosed and tested in practice. A proficient psychiatrist should have the ability to provide various types of treatment, according to the patient's need. An appropriate scientific frame of reference provides him with an accurate tool for understanding and communication. The psychotherapy of schizophrenia differs qualitatively in goal and method from the treatment of the neuroses because of the qualitative difference in the psychodynamic integration of schizotypes, as described above.

The scientific understanding of events and changes in psychotherapy requires accurate theory of psychodynamics and psychotherapy. In addition, there is an artistic dimension to therapy, and apprenticeship

methods are required for its mastery. Clinical competence depends heavily on certain characteristics of the individual therapist, e.g., empathy, insight, etc. The gifted therapist may achieve results, even when his frame of reference includes inaccuracies. Psychodynamic science, however, depends on the development of theories which are as adequate and accurate as possible. Adaptational psychodynamics represents an attempt to formulate an organized basic theory which will ensure the accurate understanding of human behavior.

Chapter 8

Other Psychoanalytic and Psychodynamic Theories

8.1 ADOLF MEYER

GEORGE MORA, M.D.

Introduction

Background and training. Adolf Meyer was born in Niederwenigen, Switzerland, on November 13, 1866, the son of a Zwinglian minister. In medical school he was influenced by the psychiatrist August Forel, Director of the Burghölzli Hospital for the Insane. Subsequently, during a year of postgraduate study in London, Meyer was particularly impressed by Hughlings Jackson's integrative views of the nervous system and by Thomas Huxley's evolutionary concepts. In 1892, following a period of further study in Paris under the neurologist Déjérine, Meyer decided to emigrate to the United States and to accept a position at the State Hospital at Kankakee, Illinois.

Early career. Three years after he arrived in this country, Meyer accepted a position as pathologist at the Worcester State Hospital, which at that time, was one of the outstanding psychiatric institutions in the United States. Shortly thereafter, he was appointed Clinical Director of the hospital and began to establish standards for taking and recording detailed case histories for all psychiatric patients. A subsequent tour of various psychiatric institutions in Europe in 1896 resulted in his adoption of Kraepelin's system for the classification of mental disorders. However, nosology was not Meyer's primary interest, for even then he recognized the importance of the psychiatrist's awareness of the dynamic factors which influenced the behavior of the patient and his life situation.

In 1901 Meyer was appointed Director of the Pathological Institute by the State of New York, and he proceeded to establish basic standards for the state hospital system. The following year, Meyer moved the Institute to Manhattan State Hospital at Ward's Island so that he might have more opportunity for clinical

observation. Concurrently, he began to concentrate increasingly on the study of psychopathology.

Basic orientation. Instead of emphasizing symptoms, Meyer focused on the types of reaction manifested by the whole individual in terms of his total life experience. In 1903, in an article entitled "An Attempt at Analysis of the Neurotic Constitution," Meyer postulated that mental disorder often had its roots in a personality imbalance which, in turn, was caused by the disorganization of habits. The "incomprehensible" symptoms of mental illness were viewed as crude and inadequate attempts by the patient to cure himself, which had to be guided rather than suppressed. Dementia praecox, which was then the area of investigation of such outstanding psychiatrists as Kraepelin and Jung, was the testing ground for Meyer's concepts. Contrary to Kraepelin's stress on deterioration as the eventual outcome in dementia praecox, Meyer believed that personality traits, such as withdrawal, preceded the appearance of the disease, and he suggested that prevention, as well as recovery, might be possible. He conceived of schizophrenia as a "twisted" maladaptation which could be understood in terms of the patient's life experience and was characterized by habit disorganization or deterioration.

Meyer recommended that an attempt be made to intervene early in the development of the illness by the patient's school, family, and community. Thus, his early interest in "community psychiatry" is noteworthy. Moreover, the first applications of the principles of social work to occupational and recreational therapy with convalescent patients, and the organization of after-care programs, were inspired by Meyer's work during this period.

In the meantime, psychiatrists in this country had become familiar with Freud's theories, largely through the efforts of Stanley Hall at Clark University. As early as 1906, Meyer evaluated Freud's study of the infantile phase of development as "pathologically important" and warned against premature rejection of psychoanalysis, although he objected to Freud's em-

phasis on the pathological and hypothetical, rather than on the healthy and verifiable aspects of mental functioning. Meyer's theory of psychobiology reflected this conflicting view.

Meyer introduced the term, "psychobiological interpretation," during a lecture on dementia praecox at Clark University in 1909, in connection with the different types of disorganizing personality reactions. In the broad context of psychobiological interpretation, Meyer explained, pathological personality reactions could be explained as regression to former, previously protective phylogenetic reactions which were incompatible with adaptation at the later time.

Meyer's Theory of Psychobiology

Basic concepts. Meyer developed the theories which were to be designated as the school of "psychobiology" during his tenure at Johns Hopkins. Here, as Professor of Psychiatry and the first Director of the Henry Phipps Psychiatric Clinic, he remained from his appointment in 1913 to his retirement in 1937. In brief, psychobiology emphasized the importance of biographical study in understanding the whole person. That is, the object of such study is the individual, whom Meyer defined as a biological unit that always functions as a person, whether alone or in groups. Although it changes constantly, the individual's "experiential continuum" enables him to maintain internal and external homeostatic equilibrium in coping with new situations. In addition, the individual's plasticity allows him a wide spectrum of differentiation in capacity and function, and a relatively high degree of spontaneity and responsiveness. Because of the complexity of human functioning, the psychiatrist who attempts to acquire a scientific understanding of his patients must have a combination of attributes: he must be a methodical investigator, biographer, artist, and educator.

In sketching the evolutionary development of the human mind, including its prehistory, largely through the process of symbolization, Meyer noted that the biographical study of man was the last discipline to pass from the stage of intuition and philosophical speculation to that of scientific investigation. This area of study, which he defined as objective psychobiology, consisted of the observation of objective facts, the formulation of predictable conditions in which these may occur, and the testing and validation of methods for their controlled modification. Instead of accepting predetermined hypothetical psychological or metapsychological constructs to account for these facts, he emphasized the soundness of "common sense."

Although an analysis of psychobiological assets may reveal the presence of a variety of factors in each individual, Meyer emphasized the basic tendency toward integration that takes place. Because Meyer believed that multiple biological, social, and psychological forces contribute to the growth and development of the personality, he concluded that psychiatrists must

study normal and abnormal behavior from many viewpoints.

Meyer conceived of the clinical value of the biographical approach to personality study as follows. It provides a practical and specific guide for eliciting individual data; a means of organizing that data; and a method for checking and reevaluating data elicited under varying conditions. Recognizing that only a fraction of the total personality could be understood at any particular time, he devised a biological-cultural formula. The denominator of the formula consisted of the total personality record or potentiality of the patient; the numerator was the particular sample of performance.

Clinical examination. For Meyer, the clinical psychiatric examination included the following components: (1) identifying the motives or indications for the examination, with particular focus on presenting pertinent details in the patient's life history, elicited through biographical study; (2) listing the obviously related personality items, factors, and reactions; (3) careful study of the physical, neurological, genetic, and social status, and the correlation between these variables and personality factors; (4) differential diagnosis; and (5) formulation of a therapeutic plan geared to each case. Meyer felt this to be the best way to reconstruct the "experiment of nature," which was defined as the reduction of events in the patient's life to the factors in a controlled experiment. In accordance with its common sense approach, psychobiology began with the data which were accessible. Symptoms were viewed as compensatory phenomena. Because data selection was necessary in any examination, Meyer called "distributive analysis" the study of all the factors in an individual's life which played a significant role (whether favorable or unfavorable) in his adjustment. The formation of better methods of adjustment by the patient, based on his understanding of past maladaptation, was termed "distributive synthesis."

In interviewing a patient, Meyer considered it better to begin by focusing on his chief complaint, which directed attention to the situation which required immediate therapeutic intervention. Later, the psychiatrist would determine the nature and extent of the disturbance in the context of the patient's over-all functioning, the previous medical history, and the role played by such factors as constitution, development, and environment. Unconscious material elicited from the patient, as well as information supplied by his family, could supplement the psychiatrist's efforts and facilitate his understanding of the situation.

As a general rule, Meyer felt that "one-word diagnoses" were inadequate in a field as complex as human behavior. Initially, he used the terms "reaction set" or "reaction type" in diagnostic classification. From the early 1920's on, however, he used the word *ergasia*, derived from the Greek word for work, *ergon*, to describe the general concept of behavior and mental activity,

and its plural, *ergasias*, to denote specific behavioral units. Ergasias were the behaviorally conceived overt and implicit products of psychobiological integration. In the normal personality, of the many potentialities available for adaptation, various "ergasias" tended to prevail, depending on the internal and external needs of the individual. Meyer defined the individual's overt behavioral response to various situations as "subject organization." He then listed the various ergasias, using a different prefix for each type. At the same time, he warned that these classifications, in themselves, were not to be regarded as diagnoses; they simply described phenomena which occur under various conditions. It should also be noted that the following list of ergasias is no longer in use but is reproduced here for historical reasons. (1) *Anergasia* (an = lacking or lost): organic brain reactions, such as general paresis and senile brain disease, in which structural and functional brain deficit and pathology alter behavior; (2) *dysergasia* (dys = difficult): syndromes due to impairment of brain function, such as the toxic psychoses and delirium; (3) *thymergasia* (thymo = affective): the affective psychoses, such as manic-depressive reactions; (4) *parergasia* (para = beside): the form of schizophrenia which is characterized by regression, abandonment of reality, and delusions; (5) *merergasia* (mero = part): partial inability to work or function, as in the psychoneuroses; (6) *kakergasia* (kakos = bad): abnormal, poor, or faulty behavior, used synonymously with *merergasia*; and (7) *oligergasia* (oligo = few or scant): mental deficiency.

Psychobiological Therapy

Psychobiological treatment, which began with distributive analysis and terminated with distributive synthesis, was not considered apart from pathology. More specifically, Meyer believed that the psychiatrist began to treat the patient at the time of their initial contact with the patient's exposition of his "problem." This did not mean that diagnosis was not essential. However, the first step in distributive analysis was evaluation of the patient's assets and liabilities. This was best accomplished through the study of his life history, on the basis of current data initially provided by the patient, and supplemented by his subsequent reconstruction of past experiences.

Meyer recognized the importance of the patient's cooperation for the success of the psychotherapeutic process: the cooperation of the patient's better self, i.e., of the healthier part of the patient's ego, was considered essential. Concomitantly, he believed that these healthier aspects of the patient's personality should serve as the starting point for treatment. Therapy was conceived of as a service performed on behalf of the patient; the therapist was obligated to utilize every available opportunity to assist the patient. The basic aim of psychobiological therapy was to help an organism, hampered by abnormal conditions, to make the best adaptation possible to life and change.

Treatment techniques. In the initial stage of treatment, the therapist's concern focused on the patient's sleep habits, nutrition, and the regulation of daily routines. It was also important at this stage to induce the patient to describe his difficulties in a concrete way, and for the therapist to use the patient's ideation and language to communicate his offer of help and advice.

Problems were approached on a conscious, rather than an unconscious level. Thus, therapy was administered in the course of ordinary face-to-face conversation, in order to implement the psychiatrist's efforts to focus on the patient's current situation and his reactions to his everyday difficulties, as well as his long term life adjustment. At the beginning of each therapeutic session, the patient was encouraged to discuss his experiences in the interval since the last interview, beginning with obvious and immediate problems. Eventually, these problems were explored in greater detail, when deeper relevant material had been elicited from the patient. This was accomplished through the use of "spontaneous association," a term used by Meyer in preference to "free association," to describe the overcoming of the patient's resistance to verbalizing his basic problems in the unbiased atmosphere of the psychiatrist's office.

The intensity and frequency of treatment sessions depended on the needs of the individual patient. The psychiatrist permitted the patient to arrange his treatment schedule or asked him to agree to a specific therapeutic program. It was the psychiatrist's responsibility to reassure the patient, so that he could function adequately between interviews. This reassurance was conveyed through casual comments and sensitive questioning.

Under the guidance of the psychiatrist, the patient analyzed his personality problems and their relative importance (distributive analysis) and then reconstructed the origin of his conflicts and devised healthier behavioral patterns (distributive synthesis). The psychobiological therapist asked the patient to formulate his life story by means of a life chart, to demonstrate his understanding of the origin of his difficulties and the means he might employ to ensure their resolution and prevent their repetition.

Meyer believed that the essential goal of therapy was to aid the patient's adjustment by helping him to modify unhealthy adaptations; these modifications would lead, in turn, to personal satisfaction and proper environmental readjustment. He called this "habit training." In the process of habit training, the psychiatrist utilized a variety of techniques, e.g., guidance, suggestion, reeducation, and direction—always with emphasis on the current life situation. Psychobiological therapy was especially valuable with psychotics, although it was also recommended for psychoneurotic reactions. And, in regard to the treatment of the hospitalized patient, Meyer also emphasized the importance of collaboration of the members of the thera-

peutic community—physician, patient, nurse, and ward group, as well as the patient's family—in providing a setting to safeguard the integrity of the patient's personality functions.

Meyer emphasized that different criteria could be used to evaluate a patient's progress and his return to normalcy, according to the concepts of different schools of psychiatry. However, he preferred the criteria of the capacity of the individual to follow a constructive regimen of work, rest, and play.

Meyer's Contribution to Psychiatry

Contribution to psychiatric training. From the opening of the Henry Phipps Psychiatric Clinic in 1913, with Meyer as director, he was closely identified with the psychiatric training program there, which produced a large number of psychiatrists who carried the concepts of psychobiology to medical schools and psychiatric clinics and hospitals throughout the world. Even after his retirement in 1937, until his death in 1950, he remained active in psychiatry.

However, Meyer was not primarily concerned with the dissemination of his theoretical concepts. A large part of his work was dedicated to providing proper training in psychiatry for medical students and residents. This training included the development of techniques for the detection and description of the behavioral signs and symptoms; such techniques provided a common basis for communication. In general, these techniques were based on Meyer's concept of psychopathology as an uninterrupted continuum of normal behavior, as an adaptive reaction occurring through temporal sequences and stages which could be elicited through careful history taking and formulated by means of a biographical life chart.

To summarize Meyer's major contributions to psychiatry, they might be considered to include: (1) his emphasis on the interactive nature of symptoms, and the unity of the individual's psychological and biological functioning, so that psychoses are described as "reactions," a definition which persists in the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association; (2) his pioneering biographical and historical approach to the study of personality; and (3) his enthusiasm for social action, especially for community psychiatry. In fact, although community psychiatry has come to the fore only recently, Meyer predicted the establishment of the community mental health center as early as 1913.

As for psychobiology, with which Meyer's name is usually connected, it was never truly a personality theory, and therefore its application declined with the death of its founder. However, the importance of psychobiology does not derive from its application as a system or theory. Rather, psychobiology is important as a trend of thought which paved the way for the acceptance of current psychodynamic concepts.

8.2 CARL JUNG

EDWARD WHITMONT, M.D.

Introduction

This description of Jung's contribution to psychiatric thought, which he called "analytical psychology" (to differentiate it from Freud's psychoanalysis) will be limited to a definition of his main concepts and formulations—his symbolic method and his views of the collective unconscious or objective psyche, the archetype, and the complex—and a brief description of his practical methodology.

Basic orientation. Jung differed from Freud, above all, in his concept of the unconscious as the original, a priori mold of the personality and not merely the repressed part. He viewed the unconscious as an original pattern of motivation which manifests itself gradually throughout life but which never can become completely conscious. Jung regarded the symbolic approach to these unconscious phenomena, i.e., dreams and other unconscious manifestations, as the most rewarding means of comprehending the "language" of the psyche and of describing its dynamics. Specifically, he believed that the psyche communicates with us through images rather than concepts and that these images take the form of analogies and parables which represent the meaning of a given situation. He regarded this "as if" method of communication as the spontaneous and original means of psychic expression, "the forgotten language of the soul."

In Jung's estimation, it is not possible to define the psyche with objective accuracy, for in any such attempt the psyche is both subject and object of the definition. Accordingly, he charted the territory of the

psyche in the language most germane to it, symbolism. He utilized the methods of modern physics and sought symbolic descriptions or working models based upon observation of the way an otherwise unknown, which defies precise description, acts in the world of matter.

However, it is important to note here that, to Jung, psychic symbols were not freely chosen, abstract designations which are attached to a specified object by convention (as a verbal or mathematical sign might be). Rather, they are genuine and organic forms of experiencing life; they extend beyond their obvious implications to take on a meaning which cannot be conveyed within our accustomed rational framework. Jung defined a symbol as the best possible description or formula of a relatively unknown fact; a fact which, although it is unknown, is recognized or postulated as existing.

In brief, the generally accepted view regards rational conceptual thought as the standard of normality, while dreams and fantasy are relegated to the level of the primitive, regressive, and even abnormal mental functioning. In contrast, Jung revealed the autonomous image world of the psyche, as expressed in dreams and fantasies, to be a vital and indispensable source of guidance and information which was not to be found elsewhere. His method of dream interpretation, which is so different from that used in other analytic techniques, originates in this radical and unique view of what he called the objective psyche.

Objective Psyche

Definition. This term replaced Jung's earlier reference to the "collective unconscious," which had given rise to serious misunderstanding and misinterpretation. Jung defined the objective psyche as nothing less than the totality of a priori psychic prefigurations and predispositions, the whole substratum of autonomous psychic functioning; and he held that this reservoir of a priori psychic existence gives birth to consciousness. In other words, he maintained that this substratum of psychic phenomena exists prior to the conscious mind and continues to function together with, or despite consciousness; it is autonomous and has laws unto itself. Although the objective psyche may subsequently contain many elements which were once conscious and have become unconscious again (through repression, for instance), the unconscious as a whole cannot be considered a mere relic of consciousness, any more than the psychic functions of animals can be considered remnants of consciousness. The autonomy of the objective psyche can be observed in the peculiarly organized character of the image and emotional drive patterns which arise spontaneously from that realm. Quite frequently, these patterns take on the character of separate personalities. Jung reasoned that if each of these "splinters,"

regardless of whether the fragment is big or small, has an independent personality, then the larger block from which they were separated must have personality autonomy to an even greater degree. He conceived of this larger segment of total personality as a concealed entity: it can be dormant or "dreaming"; it does not necessarily include consciousness.

In summary, then, the objective psyche is so labeled because it lives an independent, autonomous life prior to and regardless of consciousness and personal experience; it possesses a meaning and reality of its own, only one particular aspect of which is ego consciousness. The objective psyche is not a part of the subjective being which the individual calls "I"; rather, his subjective experience of himself is only a part—and, in fact, an incomplete and relatively inadequate part—of the encompassing wholeness of psychic existence. General, impersonal, and as yet undifferentiated, the objective psyche counterbalances individual ego personality with varieties of unconscious (and, therefore, not yet individualized) partial personalities.

The personal unconscious. Jung described what is commonly referred to (by Freudian and other schools of thought) as repressed material, that is, experience which was once conscious, but was subsequently rejected, as the "personal unconscious." Attitudes, urges, feelings, etc. that have been repressed as incompatible with one's ego-ideal appear in personalized form in dreams and fantasies as the "shadow," the alter ego, the individual's unacceptable and repressed "other" personality, which is experienced through an automatic projection upon another person for as long as it remains unconscious. But, again, this personal unconscious is only a small part of the total objective psyche.

Introversion and extroversion. It follows from this view of the reality of the inner world of the psyche that the introverted life adaptation is equal in value to the extroverted one. "Introversion," which is defined as that approach to life experiences in which the individual's predominant sense of reality derives from the actions and reactions of his inner world (thoughts, intuitions, emotions, and sensations) is regarded as complementary to extroversion. "Extroversion," in turn, is defined as the attitude in which the individual's concern with material objects and people predominates. Just as an overemphasis on introversion may result in inadequate external adaptation, extreme extroversion, which is fostered by prevailing cultural and educational values, may lead to depersonalization, loss of a sense of identity, and submersion of the individual in conformist herd psychology.

Archetypes and complexes. The two chief elements of the objective psyche are the archetypes and the complexes which surround them. The archetypes of the objective psyche are a priori energy field con-

figurations which express themselves in typical representational images and in typical human emotion and behavior patterns. They are analogous to the instinctual patterns observed in animal behavior. All psychic energy is channeled and directed into these basic forms of experience, behavior, and emotion. Thus, the archetypes constitute the predispositions of the psyche, or the basic motivations and drives around which the conscious personality will subsequently organize itself. The representational images which express the arrangements of elemental psychic life are universal images which appear in dreams in forms which are similar to past and present mythologems, such as the motifs of mother, father, child, hero, death, rebirth, or the search for treasure.

Complexes may develop as a result of long term conditioning, and/or early traumatic experience. However, their structure derives from an archetypal model; that is, they are based on "transpersonal" and universal forms of human experiencing. To illustrate, the "mother complex"—one's unique, and at times bizarre, manner of reacting to one's mother or one's way of being motherly—is determined not only by personal experience with one's own mother, but also by the universal human predisposition and reaction pattern in terms of "The Mother," by a preformed image or gestalt pattern which exists within the psyche. Jung called this preformed image the mother archetype. It corresponds to a mythological image, which is personalized in the process of being projected as an expectation onto the woman who fills this role in real life.

The mother complex develops as the result of the conflict between archetypal expectation and actual experience with the real woman (or women) who function in a motherly role. For example, a man may project his archetypally based expectations regarding the mother onto any eligible woman in his environment. He will then experience her as life- and love-giving, as protective, sheltering, all-understanding, and unconditionally forgiving; and at the same time he will see her as diminishing his life strength by means of her unfathomable wiles. She is both beautiful and ugly, attractive goddess and destructive witch. And, indeed, all these features are personified in the mother-goddesses of mythology. While no human being has all of these capacities and destructive powers, the human mother who is aware of the degree to which she represents this image can realistically embody its positive, life-giving female aspects and can reduce its negative archetypal elements to an equally realistic degree. However, should the man's relationship with his mother be problematic due to her possessiveness or cold remoteness, the negative aspect of the mother archetype (the devouring witch or dragon) may become activated and form the core of a disruptive mother complex, which forces the ego personality to flee forever from the witch that is projected upon every woman.

In summary, complexes operate as larger or smaller "splintered" personalities and represent autonomous affect-motivated patterns which are endowed with an organized structure and will of their own. More specifically, complexes (and the archetypes on which they are based) can disrupt and even submerge consciousness by replacing the rationality of the ego with their own weird images, emotion, and action patterns. If the conscious ego cannot translate the archetypal expressions symbolically, their meaning will not be accessible, and the ego cannot relate to them in a way which will utilize their energy creatively. Only through the symbolic approach can the archetypes and complexes serve the needs of consciousness and personality growth; if the archetypes are denied, then compulsive, obsessive patterns will develop, which in their extreme forms become psychotic.

Archetypal configurations. As mentioned above, the archetypes (e.g., mother, father, child, hero, etc.) are manifested as mythological or personalized images in dreams and fantasies; in addition, they are invariably projected onto other people. The archetypal configurations which are encountered most frequently are the persona, shadow, animus (in women), anima (in men), and self.

Persona. Jung used this term, which when translated from the Latin means "the actor's mask," to characterize expression of the archetypal drive toward conformity and external reality. The persona is the mask which covers the personality of the individual; it is the face he presents to the outside world, the surface which embodies his external expectations about his social role. In dreams, the persona is represented in the form of images of clothing and as problems involving dress.

Overidentification with the persona results in a pseudo ego, a stereotyped, false personality based on early values and standards of performance which emphasized the need to conform. Thus, one actually becomes the professor, judge, policeman, or society matron, rather than an individual who has adopted the role or profession of professor, policeman, or matron, etc. and gives the role its due at the necessary times. Similarly, other people are viewed not in terms of their unique individual characteristics, but as personifications of the "sister," the "doctor," a "brain," or a "rich man." If the persona is preeminent, dream images show clothing that is too tight, rigid, or armor-like.

Conversely, an inadequate persona means an inadequate adaptation to collective and social demands; hence it can represent as much of a threat to adequate ego functioning as an overly rigid persona. In such cases, dream images may show the dreamer appearing in the street or at a party inadequately dressed or naked.

Shadow. The shadow is represented in dreams as another person of the same sex as the dreamer, and it personifies the dreamer's repressed personal uncon-

scious qualities, his "other" personality. To the extent that the individual is not aware of his shadow and, consequently, identifies with it, he ascribes those qualities he rejects and cannot accept in himself to the other fellow or, collectively, to other people, e.g., minority groups, who then become the enemy.

Anima and animus. Anima and animus are archetypal representations not of personal qualities, but of predispositions or potentials—instinctual, as well as emotional and spiritual—which have not yet become personalized or entered conscious awareness. The anima and animus configurations are universal basic human drives, from which both conscious and unconscious individual qualities develop. These drives do not belong to the manifest personality, but represent "other" as yet unrealized, or recessive elements. Since they include a man's undeveloped femininity and a woman's undeveloped masculinity, they appear in unconscious imagery as persons of the opposite sex, as indicated in the use of both genders of the term: anima to denote the man's feminine aspect, and animus for the woman's masculine qualities. The anima represents the man's feminine potential which is undeveloped (to varying degrees) and, therefore, relatively primitive and unconscious. It includes his capacity for emotionality, fantasy, imagination, receptivity, and the moodiness over which he has no control. When these attributes are projected, they form his anticipations, fears, hopes, and expectations about women. Conversely, the animus, the woman's recessive masculinity, represents her potential initiative and aggressiveness, her ability to reason, her spirituality, and her capacity for activity and organization. When they are not assimilated by consciousness and, therefore, are beyond her control, the animus aspects take hold of her as dogmatic opinionatedness, self-righteous argumentativeness, and stubborn aggressiveness. When the animus is projected, it forms her anticipations, expectations, and reactions to men.

Self. A good deal of misunderstanding has arisen concerning Jung's concept of the self. In contradistinction to Freud's use of the term "self" to refer to the empirical ego-personality, Jung used the term to hypostatize a central archetype which embraces both conscious and unconscious elements, a psychic "wholeness." Since his idea of the unconscious, i.e., the objective psyche, extends to future potentialities, as well as to all current and past experience, the self, as the center of a personality that is both actual and potential, represents not only what we were and are, but also what we are still to become.

In a broader sense, the idea of the self represents the inherent "law of one's being," the archetypal drive toward individuation, toward becoming what one was meant to become, in terms of one's own nature. Jung did not regard the psyche as a *tabula rasa*, to be imprinted with environmental influences. In his view, individuality is preformed in the psyche of the neonate. Environmental influences serve to

modify, enhance, repress, distort, or fragment the unfolding archetypal potentials as they develop into complexes. Thus at various phases of development varying degrees of tension arise between the potential self and the actual ego. This ego-self tension is the underlying cause of one's sense of splitness and incompleteness; it provides impetus for the autonomous drive toward individuation, the urge to become whole, to bridge the split between the actual ego and the potential self, between what is conscious and what is unconscious.

The Ego and the Unconscious

The individual ego is confronted with the basic determinants of the objective psyche, the archetypes, namely, the typical predispositions of behavior, patterns of emotion or affect configurations, and representational images. It is also confronted with the complexes which result from the personalized modification (or distortion) of archetypes when they interact with early childhood experience, conditioning, and traumata. The archetypes and the complexes which form around them operate independently of the ego and are, to varying degrees, in conflict with the intents of the conscious personality; therefore, they are capable of causing psychic dissociation and fragmentation. The resultant threat to emotional stability can be overcome only if these archetypes and complexes are consciously confronted and understood in symbolic terms.

For example, a male patient's compulsive urge to prostrate himself and worship a woman's feet was resolved and integrated into his personality once he understood the symbolic content of his fetish. More specifically, his seemingly bizarre urge had to be understood *as if* it referred to a gap in his potential wholeness; it had to be translated as symbolizing his unrealized need to worship and adore the feminine world of emotion, fantasy, and intuition, as it exists in himself and in others, which his one-sided, rational outlook had previously devalued. Once he acquired such insight, his behavior was no longer governed by the primitive urge. The reorientation of conscious contents and values which occurs consequent to such symbolic understanding enlists the cooperation (rather than the obstruction) of the unconscious in daily life.

Process of individuation. Jung described the process of individuation as the growth and expansion of personality which occurs through realizing and becoming what one intrinsically is. This process defines the purpose of therapy for both the neurotic and the psychotic patient, and it delineates the goal of the healthy person who is seeking a clearer or deeper understanding of the meaning of life. Jung commented on this point as follows:

...psychoneurosis must be understood...as the suffering of a soul which has not discovered its meaning. But all creativeness in the realm of the spirit as well as every psychic advance of

man arises from the suffering of the soul, and the cause of the suffering is spiritual stagnation, or psychic sterility. (Psychology and Religion. *Collected Works*, vol. 11, p. 330).

Conscious and unconscious do not make a whole when one of them is suppressed and injured by the other. If they must contend, let it at least be a fair fight with equal right on both sides. Both are aspects of life. Consciousness should defend its reason and protect itself, and the chaotic life of the unconscious [should] be given the chance of having its way too—as much of it as we can stand. This means open conflict and open collaboration at once. That, evidently, is the way human life should be. It is the old game of hammer and anvil: between them the patient iron is forged into an indestructible whole, “an individual.” This, roughly, is what I mean by the individuation process.

(The Archetypes and the Collective Unconscious. *Collected Works*, vol. 9, Part I, p. 288.)

The achievement of personality means nothing less than the optimum development of the whole individual human being. (The Development of the Personality. *Collected Works*, vol. 17, p. 171.)

It... means fidelity to the law of one's own being.

(The Development of the Personality. *Collected Works*, vol. 17, p. 173.)

In so far as every individual has the law of his life inborn in him, it is theoretically possible for any man to follow this law and so become a personality; that is, to achieve wholeness.

(The Development of the Personality. *Collected Works*, vol. 17, p. 179.)

Libido theory. Jung viewed the libido as every possible manifestation of psychic energy. It is not limited to sexuality or to the power drive but may express or include these in addition to any and every other possible expression of the psyche, including the religious or spiritual urge, the urge to find meaning in life. Jung's definition of religion is not confined to any particular creed but is derived from the original meaning of the Latin *religere*, namely:

...A careful consideration and observation of certain dynamic factors that are conceived as “powers,” “spirits,” “daemons,” “gods,” laws, ideas, ideals, or whatever name man has given to such factors in his world as he has found powerful, dangerous, or helpful enough to be taken into careful consideration, or grand, beautiful, and meaningful enough to be devoutly worshipped and loved.

(Psychology and Religion. *Collected Works*, vol. 11, p. 8.)

Accordingly, analytic psychology gives conscientious consideration to the nonrational archetypal factors of the psyche as they delimit, modify, and direct the conscious ego's functioning and goals. At the same time, the individual who seriously explores the products of the unconscious finds symbols and images arising within himself which have occurred again and again in the past as part of the mythological and religious experience of people of all races, both within and outside the framework of the church. Since religion and the religious attitude arise spontaneously within the unconscious in the form of mythological representations, they are not, from the Jungian point of view, to be identified with any specific belief or doctrine. Nor, for that matter, should they reflect the teachings or convictions of the analyst. They are concerned exclusively with the individual's relation

to his own deepest reality. What they demand of him is not abstract consideration in philosophical terms. Rather, they serve to underscore further the need for a symbolic understanding of the images of his unconscious, a total psychic reorientation in terms of his concrete, everyday problems. The following segment from a case history may serve to illustrate.

A middle-aged man of decidedly atheistic convictions, in modest circumstances, had decided to leave his wife and children to marry a wealthy girl, many years his junior. After he made this decision, he had the following dream. The patient dreamed that he was about to set out on a trip to a rather out of the way destination. Rushing off hurriedly, he passed a group of respectable looking elderly men who shook their heads disapprovingly. He disregarded them, however, and pushed on. Suddenly, from out of the clouds, a huge hand appeared, grabbed him, and shoved him back to the place from which he had started.

This dream shows that the patient was well aware that what he set out to do was “out of the way” and contrary to generally and culturally accepted moral standards (the disapproving elders = Freud's superego). It shows that it might be possible for him to disregard these considerations with relative impunity and still manage to get by. Something else, however, could not be disregarded. A power or entity, visualized or symbolized as if it reached from heaven to earth, did not allow him to proceed. We may call this power the inner judge of conscience, the moral integrity of the personality, the self (as distinguished from the conscious ego), or the will of life, or characterize it in the symbolic terms of this dream image as the hand of God. All of these phrases and symbolic representations express the same thing: they refer to an entity which is both unknown and unknowable, yet objectively real; is transpersonal and supreme; has appeared in the form of many symbols and under many names; and has been instinctively acknowledged by mankind throughout the ages. The dream contains a warning that the “hand of God” would not permit the patient to proceed.

Of course, one is justified in asking whether dreams of this sort may not express the patient's own unadmitted and unconscious wishes, rather than the requirement of an “objectively real” transpersonal self, an unknowable entity anthropomorphically symbolized through the images of the objective psyche. Could this religious symbolism have been “invented” in order to furnish the dreamer with a plausible alibi for changing a plan he did not really want to go through with? Quite frequently, however, as was true in this case, the dreamer is startled, even shocked by such material. Far from fulfilling his wishes or representing any attitude he can recognize as his own, it actually makes a demand upon him and confronts him with a point of view which is apparently entirely unacceptable and opposed to his own desires and convictions.

Not infrequently, there are serious consequences when warnings of this sort are overlooked. The dis-

regarded, unconscious "other" will then obstruct and sabotage, rather than complement, the conscious personality, thus producing psychopathology which stems from varying degrees of guilt and conflict. Such observable results would certainly seem to justify acceptance of the "objectiveness" of a nonpersonal source of meaning as a working hypothesis.

Analytic Principles

The aim of psychotherapy, as Jung defined it, is to bring about an adequate adaptation to reality. But, as we have seen, he conceived of an internal, as well as an external, reality. That is, reality includes the demands of the unconscious and the as yet unrealized potentialities of the inner world of the objective psyche centered in the self, as well as one's adaptation to society. Thus, the wholeness of the human individual requires an awareness of both inner and outer demands. In general, the need for outward adaptation is well recognized and has been stressed in clinical practice; Jung's major contribution stems from his unique view of man's inner adaptation. Thus, Jung maintained that all psychic drives are amoral and ambivalent; that is, they do not fit into positive-good, or negative-bad classifications. Rather, it is our conscious attitude toward these drives (and toward archetypal meaning as well) that determines whether they will play a constructive or destructive role in our lives.

Jung's concept of psychopathology. When drives, archetypal urges, talents, or qualities are repressed or not allowed to develop, they remain primitive, undifferentiated, unadapted, and negative. And, as such, they exert a potentially threatening or destructive influence upon personality. When they interfere with reality adaptation, they manifest themselves in pathological obsessions or symptoms. However, these very same elements can be integrated into the personality and transformed into positive—and even creative—assets. Once the conscious ego is able to confront these hitherto unconscious or repressed components, once it is able to recognize their significance and inherent positive potential applications and can find ways to accord them a constructive role in life, a deepening of personality and life experience ensues. Thus, the drives, archetypal urges, etc., which, in their repressed form, pose a threat to our stability, may serve as a force for individuation and growth when rechanneled. Anger or vindictiveness may be transformed into initiative and courage; evasive thoughtlessness may become the talent for lightness and playfulness; rigidity may express itself as firmness.

Therapeutic techniques. Jung's therapeutic approach aims not merely at discipline and sublimation, but at transformation of the drives (and archetypal urges) themselves, i.e., the transformation of one's innermost being, through experiencing the objective psyche, not merely in an abstract, intellectual sense,

but symbolically, as an autonomous "other" personality, thereby effecting a reconciliation of conscious and unconscious drives and goals. This is accomplished by basing the conduct of the therapeutic process upon guidance from the unconscious itself. This, in turn, involves conscious observation and scrutiny of the symbolic "statements" of the objective psyche, as they manifest themselves in dreams, fantasies, and artistic productions, such as painting and sculpting. Of these, the dream is regarded as the most authentic, autonomous, and the "purest" product of the unconscious. Artistic productions contain varying degrees of unconscious elements, which are contaminated by deliberate conscious formulations; and fantasies stand midway between dreams and artistic productions. The "messages" inherent in these phenomena must be integrated into conscious life and tested in terms of external values and adaptations.

Interpretation of dreams, fantasies, and artistic productions. Jung's analytic technique relies heavily on the interpretation of dreams, fantasies, and artistic productions, and on a concern with the trend which emerges in the course of their continued observation. His radically unique method of dream and fantasy interpretation had its roots in his emphasis on the symbolic language of the objective psyche. As was evident in the preceding clinical example, Jung did not subscribe to Freud's concept of the dream as an expression of latent repressed wishes. Rather, he conceived of the dream as the involuntary expression of psychic process, which is not subject to conscious control, and which, therefore, presents the patient's subjective state as it really is.

The dream has no respect for the analyst's conjectures, or for the patient's views, fears, hopes, wishes, or illusions; it simply "tells how matters stand." However, as noted above, it does not present its "message" in the form of rational concepts, but in symbolic analogies. These analogies may pertain to an external object-related situation (in which case the dream would be interpreted on the "object level"), or to an inner situation, i.e., the dreamer's unconscious psychic configuration (which would call for dream interpretation on the "subject level"). Whatever its content and level of interpretation, the dream is viewed as a compensatory activity; that is, its function is to expand conscious awareness, by sending the ego a message describing a fact which is unknown but potentially vital, and which, therefore, needs to become known.

To illustrate, a patient's dream of being threatened by her sister would be investigated on the object level first. And in that frame of reference, it might be interpreted as a warning against her sister's behavior, if the dreamer happened to be unaware of her sister's true nature and could see only her loving, friendly side. If, on the other hand, the dream seemed to reinforce a conviction already held by the dreamer; if, indeed, it reflected the dreamer's obsessional paranoid

conviction, then it must be interpreted on the subject level, that is, through reference to the dreamer herself, if its message is to be truly compensatory and tell "how matters stand." Interpretation on the subject level would confront the dreamer with her own projection. More specifically, it would refer to the "sister within" (the shadow, the unrealized aspects of her personality), namely, to those qualities which the dreamer associates with her sister (e.g., jealousy or cynicism) while minimizing or being unaware of their existence in herself. However, she may also attribute positive qualities to her sister, such as imagination or artistic talent, which the dreamer herself possesses but devalues for some reason.

Goal of treatment. A decisive point is reached in therapy when the psychological situation appears deadlocked, with no rational solution in view that might bring about a reconciliation of the conflicting drives. Sooner or later, dreams or fantasies appear which indicate possible areas for progress and development which could not have been conceived of through conscious thought processes. Thus, in their search for a solution to the rationally deadlocked situation, both therapist and patient would do well to follow the images which arise spontaneously from the patient's unconscious as their guideline. The patient's resulting course of development may not conform to the therapist's standards of "normal" adjustment. However, this is not the goal of Jungian therapy. Rather, the aim of treatment is to develop the creative potentialities (even if this is only the creative potentiality for living) which lies within each individual patient. Thus, the therapist must decide in every single case whether or not he is willing and able to "stand by a human being with counsel and help upon what may be a daring misadventure." He must have no fixed ideas of what is right (i.e., "normal"), and what is not; if so, he takes something from the richness of the experience. He must try to help his patient find new meanings within, by helping him to understand what is actually happening in his objective psyche—"only that which acts is actual." To this end, the patient is not so much told about himself as put in touch with himself. He must make a constant conscious effort to grasp the significance of mediating unconscious images as they emerge in dreams, fantasies, or artistic productions, in order to bring about the creative transformation of destructive complexes.

Jung's contribution to psychotherapy. In summary, Jung's contribution to therapeutic techniques rests upon his view of psychological conflicts in terms of their symbolic significance, as well as their symptom content. Psychopathology is seen as the result of the individual's inability to integrate new adaptation needs. However, while the intensity of a psychiatric disturbance may be correlated with ego weakness, this may not be the only factor involved. A breakdown in the capacity to integrate the stream of irrational images and impulses may be caused by the

magnitude of the new life within, by the individual's unrealized potentials and talents. When viewed in this light, mental suffering can play a creative role in development, if the conscious ego can relate to it effectively.

By making accessible through its symbolism whatever views, insights, and awareness were previously hidden and unconscious, the objective psyche functions not only as the source of psychological conflict and pathology, but also as the source of psychological and spiritual guidance. Indeed, by uncovering the guiding aspect of psychological symbolism, Jung undertook far more than the task of relieving overt neurotic and psychotic symptoms. In deciphering the messages of the objective psyche, he showed us that it is possible to come face to face with the creative sources of existence and to unfold thereby the deepest meanings of life.

However, if the creative elements constellated by the archetypes are to be utilized fully, it is not enough for the individual to understand the reality of the autonomous complex intellectually. It must be existentially experienced as an autonomous reality. For it is through actually being "touched" emotionally that one is "moved" and thus changed. When the dissociation between conscious and unconscious personalities is healed and redirected, when a true dialogue develops in which both have their say, individuation can then take place; one becomes truly "one's self." This is the aim of therapy.

8.3 OTTO RANK

SIMON H. NAGLER, M.D.

Introduction

Rank and Freud: Areas of disagreement. Rank rejected many aspects of Freudian theory and, concomitantly, Freud considered Rank's concepts to be in conflict with the basic propositions of psychoanalysis. The nature and extent of these differences are described in further detail below. As a means of orienting the reader to the Rankian theory of personal-

ity and psychopathology, it may be summarized briefly as follows.

In general, Rank and Freud might be said to have been on opposite theoretical poles. Rank's ideas were relativistic, voluntaristic, and humanistic, in contrast to Freud's mechanistic, deterministic and reductionistic concepts. More specifically, their theoretical differences stemmed, first, from Rank's emphasis on the birth trauma as the crucial factor in the etiology of the neuroses and his concomitant negation of the crucial role played by the Oedipus complex. A second point of theoretical difference involved Rank's concept of the ego as an "autonomous representative of the will," in contrast to Freud's concept of the ego as subservient to the id.

Rank also differed with Freud in regard to psychoanalytic therapeutic techniques as well. In keeping with his theoretical orientation, he emphasized a dynamic relationship between patient and therapist rather than the classical psychoanalytic interpersonal distance and focus on interpretation. He advocated flexibility on the part of the therapist, rather than adherence to the rigid rules which then governed the classical psychoanalytic treatment situation. In addition, Rank concentrated on the patient's present difficulties, rather than trying to foster insight into his past, as advocated by Freud.

Early contact with psychoanalysis. Otto Rank was introduced to Freud by Alfred Adler as a young student of 21, and shortly thereafter he became a member of the "Committee." Recognizing his brilliance, Freud stated that he had acquired in Rank a "zealous and dependable secretary and a faithful helper and co-worker." Rank was encouraged to continue his university studies and "to devote himself to the non-medical side of psychoanalytic investigation," because of his particular interest in art, philosophy, and the problem of creativity.

Dissension and independence. Rank remained a member of Freud's inner circle until 1926, long after Adler and Jung had left the "Committee" to establish their own "schools." His departure from the orthodox camp had begun in the early 1920's, however, when he questioned the wisdom of lengthy analyses, which he considered the result of Freud's insistence on intensive investigation of each case, to the neglect of the patient's current therapeutic needs. He also questioned the value of the psychoanalyst's passive role in relation to the course of treatment, and he began to experiment with short term therapy and to set time limits for the termination of treatment. These changes in practice led to new insights and further theoretical deviations. However, Rank's final break with Freud was precipitated by his publication in 1923 of *The Trauma of Birth*.

Freud himself espoused the concept of birth as a traumatic situation which is related to anxiety. He expressed these ideas in many of his writings, and they are explicitly stated in a lecture on "Anxiety"

in his *A General Introduction to Psychoanalysis*. His opposition arose at least in part in response to Rank's hypothesis that all of life consists of complicated attempts to undo birth trauma and also to the fact that Rank assigned it a crucial role in the etiology of psychopathology. Also, Freud's opposition was directed to the central role accorded the relationship of the child and his mother in psychic conflict, so that all other conflicts, including those deriving from the oedipal situation, merely mask the essential conflicts concerning birth.

Basic orientation. In evaluating Rank's theory and therapeutic techniques, several important factors must be noted. First, Rank was not a systematic theorist, and he did not share Freud's desire to elaborate a comprehensive theory of personality. While Freud ultimately conceded the fact that the available scientific knowledge was not yet sufficient to permit such a finished system, apparently Rank was much more inhibited by these limitations. Also, Rank was influenced by his lack of medical background. As he had been trained in philosophy, psychology, art, and history, his theories were not elaborated along nosological lines or related to genetic factors. Nor was he bound by the medical tendency to conceive of neurosis as an illness. Consequently, his attempts to find a biological basis for his theory of the birth trauma were soon overshadowed by his concern with the personality as a whole, i.e., the self. Thus, his vocabulary is that of philosophy and religion, rather than medicine and scientific psychology.

One must also consider the various phases in the development of Rank's ideas. Up to the time he differed with Freud on technical problems of therapy, he had followed basic Freudian tenets, more or less. And, in fact, although *The Trauma of Birth* was a significant break with tradition, it was still in the Freudian "spirit," for, as mentioned above, Freud himself had formulated the concept of birth as a psychically significant experience earlier. However, after 1926, Rank became increasingly critical of psychoanalysis and finally reached the point where he no longer considered himself a psychoanalyst.

Personality Theory

Rank conceived of personality within a frame of reference which emphasized human values, such as religion, art, etc. He stressed the dynamic dualism in life, the polarities of male and female, individuation and conformity, impulse and inhibition, etc., eschewing the one-sided approach which he considered characteristic of Freudian formulations. Accordingly, Rank's will psychology is essentially an ego psychology, in which the ego functions as an "autonomous representative of the will."

Concept of will. The concept of will is, in fact, the core of Rank's psychology, and the problem of willing is "the central problem of the whole question of personality, even of all psychology." Rank considered will

to be "a positive guiding [force for the] organization and integration of self, which utilizes creatively, as well as inhibits and controls the instinctual drives." This concept can best be understood if it is considered in terms of its development, beginning with its first manifestations.

Trauma of birth. Freud had emphasized the powerful physiological reactions of birth as the prototype of later anxiety; but Rank correlated anxiety with separation from the mother or, more specifically, with separation from the womb, which represented the source of effortless gratification. He further hypothesized that this painful expulsion results in "primal anxiety," which is then subject to "primal repression." Thus, any subsequent desire to return to the position of "primal pleasure" will give rise to anxiety. In a broader sense, however, Rank postulated that all human mental functioning has its origin in the anxiety precipitated by the birth trauma. For, thereafter, any change from a pleasurable to a painful situation will give rise to the psychical quality of emotion or feelings of anxiety. In terms of development, Rank suggested that childhood was devoted to the mastery of the birth trauma, although the original, or "primal" anxiety had been displaced onto other situations and objects. Thus, the anxiety experienced in childhood actually represents an attempt to abreact the original traumatic experience.

As the result of the trauma of birth, separation is the most dreaded of human experiences, and the central human conflict derives from the wish to return to the womb, on the one hand, and the dread of this wish because of the anxiety it arouses, on the other. In this frame of reference, weaning is not the frustration of a component instinct (orality); rather, it represents another separation from the mother, with all the anxiety which accompanies such a separation. The frustration of orality, then, is secondary to the fear of separation. And genitality—for the male, at least—is the avenue of return to the mother. The female, on the other hand, can achieve this goal only through identification with her father or brothers, or her own child.

Infantile sexuality. On the basis of his theory of the birth trauma, Rank reinterpreted other Freudian concepts. Thus, the basic psychoanalytic concept of infantile sexuality was reinterpreted as the child's concern with where he came from, and the anxiety which surrounds his desire to return. Thus the boy clings to the notion that all human beings have a phallus, in order to avoid the primal anxiety which is associated with the knowledge of the existence of female genitalia, and, concomitantly, homosexuality is rooted in the dread of the female genitalia. Female penis envy is conceptualized as a reaction to the possession of sexual organs and is similarly associated with the primal anxiety.

The masochist transmutes the pain of birth into pleasure. The sadist merely expresses the boundless

resentment of one who has been expelled from paradise. The exhibitionist seeks a repetition of the nakedness of the intrauterine Garden of Eden. And, finally, the theory of the Oedipus complex was reformulated as the result of the attempt to master birth anxiety by accepting the mother's genitals as a source of pleasure, rather than pain and anxiety. Sleep, dreams, and even cultural phenomena were similarly explained in terms of the birth trauma and the persisting desire to return to the mother's womb.

Guilt and fear. Separation, which is basic to the development of individuality and the creation of an autonomous will or ego, begins with the act of being born and physical separation from the mother. In the course of normal development, the child learns intellectually and emotionally that he and his mother are separate individuals. Both the child and the adolescent may assert themselves negatively in order to "define" themselves. In this way, the child learns that he can say "no" to his parents, and even to his own impulses. However, this counter-will, which is essential to the process of individuation, tends to destroy the unity with others which is equally desirable. And so it tends to arouse feelings of guilt. Rank called the guilt which stemmed from this source "ethical guilt," to differentiate it from the "moralistic guilt" aroused by behavior which is contrary to social commandment. In addition, the process of achieving individuality is beset with life fear, that is, the fear of giving up the support and comfort of symbiotic relationships, analogous to that of the prenatal state. But the developing individual is assertive and potentially creative and views any regression to the womb as a loss of individuality and a threat to "life." This is manifested in the death fear, which drives the individual toward greater effort, just as life fear inhibits. This polarity between the drive toward individualization (which is impeded by life fear) and the drive toward symbiosis and dependency (which is counteracted by the death fear) points up the fact that fear is potentially constructive and not necessarily crippling; that resistance can represent the constructive power of will. Obviously, the ideal is the constructive, creative integration of these opposing trends.

Impulse, emotion, and will. Rank characterized the personality chiefly in terms of impulse, emotion, and will. The child's impulses seek immediate discharge and gratification. Emotion arises because of the blocking of an impulse, from without or within. But the real emotional life of the individual can develop only at the stage of the formation of the will—when impulses are "positively and actively placed in the service of the ego," when they are "under the dominance of the ego," instead of its master. When he learns to master his impulses, as in toilet training, the child begins the process of will development. The will, which is born out of the need to master one's impulse life, is also turned outward and manifested as "negative counter-will in the form of stubbornness, willful-

ness and disobedience." Inhibition and denial are other expressions of negative will. However, Rank also emphasized the creative nature of will, the "creative will impulse," shorn of its Freudian sexual character.

Process of individuation. The individual goes through three stages in the process of individuation. During the first stage he wills for himself what had previously been determined for him by the values of his parents and society, or by his biological needs. The next stage is one of conflict between will and counter-will, in which the individual seeks to construct his own ideals, standards, and goals. The third stage is characterized by a truly autonomous ego, capable of creative utilization of powers and ideas.

The so-called average "normal" man is fixed at the first stage. There is a relative harmony of personality functioning, but there are few possibilities for creativity. The ideal is to be like others. The second stage, that is, the stage of conflict, gives rise to the "neurotic," with his tendency toward self-criticism, inferiority feelings, and guilt. He feels estranged from society, the ideals of which he cannot accept, but he is unable to create his own values, for that would require his self-acceptance. In general, the ideal is to function in opposition to the wishes of others.

The third stage of individuation represents the highest integration of will and spirit. Creativity is pre-eminent. The individual who has reached this level of development accepts his own ideals and values without having to impose them on others. The ideal is to be what one's self is. The ego is not helplessly driven by a Freudian id or restrained by a Freudian superego. It is the autonomous representative of the will, in terms of a self-constituted ideal. Rank felt that Freudianism deprived the human personality of its inherent consciousness and potential autonomy, responsibility, creativeness, and ethical sense of duty.

Personality development and individuation are also influenced by two kinds of emotional constellations. These include the uniting or love emotions (love, tenderness, etc.), and the separating or hate emotions (pride, scorn, anger, etc.). The latter prevent the formation of the love emotions. The former lead to a "beneficent release of will," while the latter cause a "hardening" of the will. The love emotions lead to a surrender of self-will, a yielding to the will of another. "In love and through love, whether it be divine or human, the individual can accept himself [and] his own will because the other does." On the other hand, force or "will compulsion" works destructively. Sexuality is the only natural method of healing, or at least of alleviating the primal ethical guilt, because sexuality transforms the negative will into the strongest positive expression of will.

Theory of Psychopathology

As mentioned earlier, Rank was not concerned with psychiatric nosology. References to various forms of neurosis which are scattered throughout his writings

are presented chiefly within the framework of personality types. In addition to the "normal" man, Rank identified the artistic or creative type, the neurotic type, and the antisocial (criminal and psychopathic) type.

In the creative type, will is the organizing principle. Inhibition prevails in the neurotic; impulse is pre-eminent in the antisocial individual. These types are characterized by an imbalance of the various motivational trends discussed above. For example, Rank felt that the artist reconciled separation or individualization and the need for union in an essentially constructive manner. On the other hand, the neurotic is a frustrated artist type, who has failed to achieve an integration of the opposing trends in life but cannot take the easy (average) way out of the dilemma. Unable to adopt the approach of the average person, he seeks one of two alternate paths: he may become completely involved in trivial experiences, to avoid the pain of an independent act of willing, or he may become unduly compliant or consistently rebellious. The neurotic is dominated by a fear of life. He preserves a sense of wholeness by his totalistic, overwhelming relationship with others. Finally, the neurotic may become the detached antisocial type in an effort to maintain his ego intact. The death fear is dominant. Such an individual dreads the loss of individuality threatened by any union with another.

Therapeutic Techniques

The core of Rank's therapeutic technique, which is known as will, or relationship therapy, is the concept of relationship. Rank emphasized the relationship between patient and therapist; the emotional dynamics experienced in the therapeutic situation; new developments in the therapeutic situation; attention to the form or pattern of experience, as opposed to the content; and, finally, the special device of end setting, i.e., the establishment of a time limit for the treatment.

The goal of treatment is to help the patient to accept his separateness and will without guilt. Therefore, resistance is accepted as a valid expression of will. Even hostility is to be understood and accepted as an expression of counter-will, directed against the trend toward union and dependence. However, the therapist does not merely tolerate the hostility but utilizes it to help the patient to overcome his life fear and gain the courage necessary for separation.

The recognition and utilization of the life and death fears is stressed in Rankian therapy. Progress in therapy, leading to independent acts, may arouse the death fear as well as the primary life fear. Initial success may lead to an intensification of moralistic guilt. The patient must feel the support of the therapist in his new ventures toward independence, even when they do not meet with the therapist's full approval. In brief, throughout the period of therapy, the patient is given quiet assurance that he can be loved without feeling dominated.

But too much acceptance or "love" tends to activate death fear, since neurotics simultaneously seek and fear close union. An increase in the death fear ultimately leads to an intensification of the drive toward independence, a potentially healthy cycle. However, the therapist must be aware of the death fear early and reveal it to the patient, to minimize the swings between trust and fear.

Therapy seeks to develop a more reality-oriented attitude and behavior in the patient. This functionalist view leads to rapid introduction of the reality factor into therapy. Because the neurotic seeks to establish total relationships, the Rankian therapist tries to encourage a more realistic partialization through consistent examination of the real life situation, past and present. Furthermore, the realistic limitations of the therapeutic situation are stressed. The therapist accepts the will of the patient with limits consciously understood by both. The therapist attempts consistently to disassociate himself from the inappropriate, repetitive role assigned to him from out of the past, thereby bringing reality into the therapeutic process.

As soon as a good working relationship is established, however early in the treatment, a definite date for termination of therapy is decided upon, subject to change. This technique militates against the excessive dependence on the therapist which is so common in Freudian therapy. Consequently, the patient accepts responsibility for change. "Cure" is not some remote eventuality. Advance awareness of the time of termination makes the event less traumatic, "less reminiscent of the primal birth trauma."

Current Status

Although no Rankian school or training institute has been formally established, Rank's concepts have had a significant influence on American social work theory and practice (which is rivaled only by the orthodox Freudian orientation). Thus, Rank's theories have formed the nucleus for the Philadelphia, or "functional" school of social work. The University of Pennsylvania School of Social Work has been the center for the dissemination of his ideas, which are particularly suited to social work practice (e.g., short term therapy, a focus on reality factors and current life situations, etc.). Rank's influence is also evident in related areas of practice, such as guidance, counseling, and various forms of group and community work. Finally, recent trends in individual psychotherapy, such as greater activity on the part of the therapist and increasing emphasis on short term therapy, may also be considered the result of Rank's pioneer innovations.

8.4 MELANIE KLEIN

SIMON H. NAGLER, M.D.

Introduction

"English" versus "Continental School" of psychoanalysis. The areas of disagreement between the "English School" of psychoanalysis (as represented by Melanie Klein), and the "Continental School" (as represented by Anna Freud, and classical psychoanalytic theory) may be delineated as follows.

In contrast to orthodox psychoanalytic theory, which postulates the development of the superego during the 4th year of life, Klein maintained that a primitive superego is formed during the 1st and 2nd years, the stage of infantile anxiety and aggressiveness.

Klein believed that aggressive rather than sexual drives were preeminent during the earliest stages of development. It is the presence of these aggressive and sadistic impulses and the fear of retaliation which give rise to the primitive superego described above.

Klein maintained that children 2 years old could be treated analytically. The couch and free association could not be employed. However, the child might walk about, talk, play, tell stories, describe dreams, etc., and all this material was available for direct, deep interpretation by the analyst from the outset. Such interpretations could serve to allay anxiety. Moreover, the young child is capable of forming a transference. Finally, the cooperation of the child's parents is not crucial for the success of treatment, since little significance can be attached to the reality situation in any event. In contrast, Anna Freud emphasized the importance of parental cooperation, and of environmental factors in general, and advocated the treatment of young children by classical techniques which have been modified to suit the capacities of the child.

In contrast to Anna Freud, Klein believed that environmental factors played a relatively minor role in development.

Finally, Klein deviated from classical psychoanalytic theory most sharply in her formulations concerning the Oedipus complex. The onset of the oedipal conflict was traced to the earliest months of life. Further, she believed that the child became aware of parental coitus during the 1st year of life, and that this awareness led, in turn, to a wide range of sexual and aggressive fantasies.

In summary, then, Klein's formulations concerning the pre-oedipal stages of development, the superego, and fantasy in infants provoked controversy. Her later ideas, particularly her hypothesis concerning a "depressive position" in the infant, which was considered central to all mental development, were considered major deviations from orthodox Freudian theory.

Klein's intricate theoretical structure developed in two phases. The first phase ended with the publication of *The Psycho-Analysis of Children* in 1932; the second began with her classical paper on the manic-depressive states in 1934.

Personality Theory

First phase. The concepts which were formulated during the first phase of Klein's work emphasized the infant's autoeroticism and primary narcissism. She considered the infant capable of object relations, despite his poorly defined ego boundaries. Toward the middle of the 1st year, the infant's oral frustration gives rise to his unconscious awareness that his parents enjoy sexual pleasures, which is initially conceived of in oral terms. This awareness, in turn, produces oral envy and increased instinctual oral sadism, which stimulate oedipal impulses. At first, these impulses take the form of a desire to penetrate and destroy the mother's body. The child hopes thereby to incorporate orally the father's penis, which he fantasizes as having been incorporated by the mother.

In the girl, the impulse to destroy the mother's body and its contents in various cruel ways gives rise to the fear that her own body will be destroyed in retaliation. In the boy, these aggressive impulses produce castration anxiety. The primitive superego emerges at this stage of development. The incorporated penis serves as a defense against the child's sadistic impulses. These impulses are also projected onto an external object, which is subjected to oral-, urethral-, and anal-sadistic attack. This external object is first represented by the mother's breast; the infant's sadistic impulses are then directed against other parts of her body.

The child also introjects "bad" objects, i.e., those objects which cause the child pain. These evoke a cruel superego which causes severe anxiety. Therefore, in the early anal-sadistic phase the child seeks to "eject" its superego and even its id. At this time, there is confusion between the fantasied and real dangers of the bad objects, but ejection of the superego paves the way for the introjection of "good" objects which provide pleasure and satisfaction.

These early anxieties and defenses are modified by the development of libido and real object relations. In the girl, the turning from the mother's breast to the father's penis is a precursor of the oedipal situation. A similar reaction in the boy may lead to homosexuality unless a reorientation toward the mother occurs. As mentioned above, the ejection of the super-

ego in the early stage of anal development permits the reintroduction of good objects and alleviation of anxiety phobias, which have a paranoid, projective character. In the later anal stage, the superego is no longer ejected; anxiety turns into guilt, and obsessional behavior appears. The infant's belief in creative omnipotence conflicts with his destructive or excretory omnipotence. Obsessional activity is a further defense against early masturbatory impulses, which are mobilized to deal with sadistic oedipal impulses. The normal mechanisms of play augment the pathological defenses, and the creation of a realistic ego-ideal is begun. The development of the libido and superego ceases at the onset of latency. Klein believed that the progressive stages of libidinal development represent the victory of the libido in its struggle against the destructive impulses.

Second phase. The second theoretical phase revolves around Klein's concept of a "depressive position," which she postulated as central to the child's development and its later capacity for love. As noted above, the infant's development is largely regulated by the processes of introjection and projection. The child introjects good and bad objects, and the latter are conceived of as dangerous to the ego. A paranoid position automatically develops at the age of about 2 to 3 months. Specifically, projection is employed as a defense against internal as well as external persecutors. Since the infant is in the oral phase of development at this point, the aggressive fantasies projected onto the mother are those of biting, tearing, and sucking out.

At the time of weaning, the infant begins to recognize the mother as one person, both good and bad, and becomes concerned about the threat to the introjected good object, now the loved object, from the introjected bad object and from the id. There is also a danger that the good objects will be expelled along with the bad. This evokes an increase in the introjection of good objects and a need to make reparation for the destroyed objects. The child is filled with anxiety lest the love object be lost due to his own destructiveness. Whenever the mother makes the child angry, the good internal object is threatened with destruction. This conflict is the basis of the depressive position, in which guilt arises as the precursor of conscience. The guilty child uses magic in an effort to convert the bad mother into a good one, and to protect the introjected good objects against the bad.

Owing to the suffering, discomfort, and anxiety which accompany the depressive position, the infant is prone to revert to the paranoid position, in which feelings of omnipotence, overactivity, and denial of reality may be used as defensive measures, along with projection of internalized bad objects and denial of external ones. Eventually, the perfect good mother and the unrealistically dreadful bad mother merge into the image of the realistic one. According to Klein, the

real aggressiveness of the parents is unimportant as compared to the aggressiveness which the child projects upon the parents as a result of his own innate destructiveness. Thus Klein's theoretical formulations served to underscore the extent of man's innate aggressive instinct (postulated by Freud as the death instinct). Only psychoanalysis can eliminate (or, at least, diminish) this aggression and the anxiety it gives rise to, and the mutual reinforcement between man's hate and man's fear. Concomitantly, if analysis does not reach and work through this stage of infantile anxiety and sadism, it must be considered incomplete.

Klein's theories were inferentially based on her psychoanalytic treatment of very young children through play technique. Her critics considered her formulations clinically unsubstantiated and described her concepts as "subjective fantasy," "speculative," "hypothetical," "metaphorical," "dogmatic assumption," and "confusion of hypothesis with fact."

Theory of Psychopathology

Freud maintained that infantile anxiety could be epitomized as the loss of the loved person, particularly in the girl. In the boy, castration was the chief source of anxiety. Klein considered these phenomena to be later modifications of anxiety which arises at an earlier stage of development. As mentioned earlier, in the boy, the earliest anxiety situation arises from the attack on the mother's body with its incorporated penis. The infant's extremely cruel superego perceives the parents as sadistic. Consequently, the girl's sadistic attitude toward the mother's body gives rise to profound anxiety lest she suffer the same fate.

Klein considered sadism a determining factor in mental conflict. The paranoid and depressive positions were fixation points for possible subsequent psychotic disintegration. She believed that the presence of excessive anxiety in infancy and the predominance of a very severe superego from the period of its genesis were the fundamental determinants of subsequent development of disturbances of ego development and psychosis.

The ego deals with the depressive position in two ways. A flight to the good introjections carries with it the danger of a later denial of reality and schizophrenic psychosis. A flight to the external good object is the characteristic forerunner of neurosis and a possible weakness in ego functioning with marked dependency on the object. Inability to deal successfully with the infantile depressive position may lead to the dominance of one of these mechanisms. Again, failure to identify with the introjected and real love objects can result in psychotic disorders, such as paranoia and manic-depressive states. The persistence of an extremely primitive superego may account for the antisocial personality.

Therapeutic Applications

Hug-Hellmuth first suggested that the play of children might replace the free association technique which was the basis of the analysis of adults. Klein developed such an "analytical play-technique," employing small toys of a primitive type, such as little wooden men and women, carts, motor cars, trains, houses, paper, pencils, and scissors, which were usually placed on a low table in a play room.

Careful observation revealed that the child expresses its fantasies and real life experiences in a symbolic fashion through its play with these simple toys. This play can be analyzed in the same manner as a symptom or dream may be, taking into consideration the meanings of the separate symbols and the mechanisms of the dream work. The play elements are interpreted to the child in minute detail. The child also talks while he plays, and these words have the value of the associations produced in the classical free association technique. Children readily accept the interpretations offered.

For a successful treatment of a child, however young, Klein believed that the child should use language in the analysis to the full extent of his capacity. However, the direct interpretations described are adjusted to the child's level of development, in terms of speech and thought, to facilitate comprehension. For example, if the child talks about a swing which dangles and bumps, this is interpreted as reflecting his preoccupation with the way "Daddy's and Mummy's thingummies bump together." A child, 3 years old, is reported to have accepted this interpretation without the slightest difficulty.

Klein believed that children form positive and negative transferences in the classical sense. Negative transference is manifested by fear in the younger child, and by mistrust, dislike, and reserve in the older child. As anxiety is resolved, through play and its interpretations, pleasure in play is renewed and positive transferences are formed. Resistances which are difficult to resolve may occur if anxiety and guilt are released from the deeper psychic layers. In general, however, action, which is more primitive than thought, is the child's chief mode of expression. As a result, the child often reveals experiences spontaneously and directly through action, which the thinking adult can only recall through "reconstruction."

Current Status of Kleinian Theory

Melanie Klein's followers have continued to practice and disseminate her theories since her death in 1960. The so-called "English School" has gained the support of such prominent British analysts as Susan Isaacs, Joan Riviere, and D. W. Winnicott. Ernest Jones was Melanie Klein's staunch supporter from the outset. In the United States, however, the traditional concepts of classical psychoanalysis, as applied in the treatment of children, and as represented by Anna Freud, have continued to prevail.

8.5 WILHELM REICH

SIMON H. NAGLER, M.D.

Wilhelm Reich completed his formal medical training at the University of Vienna in 1922 and quickly rose to prominence in the psychoanalytic movement. In the late 1920's, as director of the Vienna Seminar for Psychoanalytic Therapy, he initiated searching discussions of analytic technique, which subsequently paved the way for modern ego psychology. But for most of his career, he was deeply involved with the quest for the biological basis of the libido theory. Unfortunately, in this search, he made numerous bizarre and pseudoscientific claims in the course of time, including among these the "discovery" of orgone energy as the basis of life.

According to classical psychoanalytic theory, character represents a habitual and relatively constant reaction which reflects the way the ego combines its various tasks in order to find a satisfactory solution to the conflict between instinctual demands and environmental forces. Reich placed special emphasis on the influence of social forces in determining character structure, particularly on their repressive and inhibiting effects.

This view of character structure as socially determined is currently widely accepted. However, Reich's early social and political views were considered rather "radical," and his efforts to apply these views to psychoanalytic theory, which was supposed to be "nonpolitical," were strongly opposed. First indications of a possible estrangement on this score appeared in 1932 when, to Freud's great distress, Reich published an article in which he advocated the amalgamation of psychoanalysis and Marxism. Reich's continued political fanaticism led to increasing personal and scientific estrangement from Freud until in 1936, he resigned from the International Psychoanalytic Association.

Nevertheless, neither the extremism of Reich's early social and political convictions, nor the bizarre pseudobiological claims he made subsequently can diminish the significance of Reich's contribution to the body of psychoanalytic theory. In addition, his

early interest in political and social forces as an influence on human development were an important stimulus for the development of the cultural schools of psychoanalysis. Thus, his hypothesis concerning character structure and the technique of character analysis have been further expanded by Horney, Sullivan, and Fromm.

Theory of Character Structure

Definition. It should be noted that Reich's theoretical contributions with regard to character structure were made within the framework of Freud's libido theory. Reich's basic concept is that character is a defensive structure, an armoring of the ego against both instinctual forces within and the world without. It is the individual's characteristic manner of dealing with these threats. As a defense which becomes an automatic mode of reaction, it acquires a rigidity which produces a loss in psychic and physical elasticity. The degree of persisting elasticity will determine the difference between the healthy and neurotic personality. The affect-inhibited compulsive personality is the prototype of the rigid, neurotic character.

At the core of the formation of character are the incestuous wishes and their inevitable frustration. Thus, character formation represents an attempt to resolve the conflict. It is precipitated by the fear of punishment which is produced by early sexual education. Society imposes its demands for a certain solution which, in turn, produces a certain kind of character structure. It is through its repressing effects on the libidinal needs that society establishes its authoritarian order: "Character structure is the crystallization of the sociological process of a given epoch."

Character formation. The rigidity of the ego is the result of several processes. First, there is an identification with the frustrating person and his prohibitions. The aggression aroused by the frustration then gives rise to anxiety, which inhibits motor expression and leads to the inhibited nature of the character. The ego employs libidinal energies to ward off the prohibited sexual impulses. "Character armor" thus formed serves to alleviate the pressure of the repressed id forces and lends strength to the ego. But the armoring may also become the basis for later neurotic conflicts and symptoms, for the determining pathogenic factor is not the conflict but the manner in which it has been solved. The solution, in turn, is largely determined by society, i.e., the family, that is, by the intensity of the fear of punishment aroused in the child, by the degree to which instinctual satisfaction is allowed, and by the character structure of the parents themselves. The outcome of the oedipal phase determines whether the individual will be capable of a satisfactory sexual life, free from neurotic problems. When the ego is excessively rigid, there is an increasing stasis of sexual energy which, eventually, can no longer be controlled by reaction formation. Neurosis can only be prevented by the develop-

ment of a character that permits genital sexual gratification.

The genital versus the neurotic character. The final quality of character structure depends on the stage of libidinal development at which character formation was most decisively influenced and on the degree of sexual stasis produced. The genital (or healthy) character differs from the neurotic character in that the genital character employs genital orgasm and sublimation to bind anxiety, while the neurotic character employs pregenital forms of gratification and reaction formation. In the neurotic character, the basic infantile instinctual conflict remains unresolved beneath rigid, automatic character attitudes, which are reflected in stereotyped postures, facial expressions, tones of voice, and patterns of mobility.

Theory of Psychopathology

Reich described several types of pathological character formation, such as the hysterical, the compulsive, the phallic-narcissistic, the masochistic, and the neurotic.

The hysterical character. This type of character is the result of fixation at the phallic phase of libido development. This character is strongly expressed in bodily behavior. Movements are soft and sexually seductive, with a special kind of agility. The hysterical character has little tendency toward sublimation or reaction formation. There is little actual sexual satisfaction and little anchoring of sexuality in the character. Sexual tensions are discharged somatically or in the form of anxiety.

The compulsive character. The compulsive character is orderly and thrifty and tends to ruminate. Outwardly, he is extremely controlled; inwardly, he is distrustful and indecisive. His affective reactions are diminished almost to the point where affect is completely blocked. These characteristics are the result of fixation at the anal-sadistic level, due to overly strict or premature toilet training. The strong inhibitions which are created at this stage interfere with progression to the genital or phallic phase and, instead, bring about a regression to the earlier stage of anal interests and aggression. In latency, anal-sadistic reaction formations are intensified to form the final character.

The phallic-narcissistic character. The phallic character does not regress to the passivity of the anal phase. Rather, he is confident and arrogant. Moreover, these traits plus aggression and sadism are manifested overtly since reaction formation is absent. He is attractive as a sexual object, although he may be orgasmically impotent. The male always has contempt for the female and has great phallic pride, but the phallus is in the service of aggression, not of love. The formation of this character type is usually attributed to frustration of the child's attempts to win the love object through display of the phallus at an early stage of development, and his

consequent identification with the rejecting person. For such a man, the sexual act becomes a demonstration of sexual potency, as well as a means of degrading or destroying the woman.

The masochistic character. Reich disagreed strongly with Freud's concept of a death instinct, and he was particularly opposed to Freud's reference to the death instinct as the basis for masochistic phenomena. Instead, the masochistic character, according to Reich, is the result of the repression of exhibitionistic impulses at the onset of the genital phase of development. Typical masochistic character traits include a chronic sense of suffering, a tendency toward complaints and self-depreciation, and a compulsion to torment others, which results in self-torment. Also included in this character is an awkward manner in dealing with people. However, the masochistic character rarely develops a masochistic perversion. Reich believed that the specific psychodynamic basis for the formation of the masochistic character was a fear of an increase in pleasurable excitation. This fear immediately inhibits any strong pleasure sensation and converts it into pain. Thus it constantly adds to the store of rejection and displeasure which the masochistic personality feeds upon. Actually, the masochist has an excessive demand for love, plus an unusual vulnerability to anxiety in the face of frustration. The masochist, because he projects his own insatiable demands, gives what he would like to receive.

The neurotic character. Reich distinguished several phases in the development of the typical neurosis. During the infantile phase of development, there is a conflict between the fulfillment of libidinal needs and their frustration, in the course of which these needs are repressed. A breakthrough in this repression, through the formation of a phobia, for example, leads to a weakening of the ego. The phobia is overcome by a neurotic character trait. When adolescent conflict is complicated by the inadequacy of the character armor, the phobia, or a corresponding symptom, will reappear. Reich considered the character neurosis to be more serious than the symptom neurosis.

Treatment

Reich's most enduring contribution, the technique of character analysis, is based on his hypothesis that certain resistances are inherent in the character structure of the neurotic patient. These resistances are evident in the patient's specific ways of acting and reacting and may take the form of extreme passivity, ingratiation, argumentativeness, arrogance, distrust, and certain motor activities. These neurotic resistances must be eliminated before the unconscious infantile material from which they derive can be recovered through the classical techniques of free association and dream analysis. Therefore, every analysis must include a character analysis.

Character resistance. Character traits are much more complex than symptoms and are more easily rationalized. As a totality, they form a compact resistance against therapeutic endeavors. The nature and extent of character resistance will vary from patient to patient of course; however, it remains qualitatively unchanged in any single patient until it disappears with the neurosis. The character resistance is separated out from the total analytic material and resolved by interpretation, rather than education to analytic candor and cooperation which is elicited through exhortation and persuasion. The patient is repeatedly confronted by his character traits until he begins to experience them as painful symptoms or foreign bodies requiring removal.

The analytic process. Thus, there are two phases in an analysis. During the first phase, there is a focus on character analysis, or "education to analysis by analysis." Once the character resistance has been diminished or removed, the second phase begins, with its emphasis on the analysis of repressed infantile material so that the libido may be freed to form a genital fixation. It is important to note, in this context, that, in contrast to the culturalists, who consider character analysis the main objective of therapy, Reich viewed it as an essential preliminary step toward the main task of analysis, namely, the working through of repressed infantile sexual material.

Reich made other contributions to technique within the framework of his theory of character analysis. Thus, he emphasized the danger of overlooking a negative transference which the overly obedient patient of the passive feminine type or the affect-blocked compulsive type might conceal behind a positive facade. He also warned of the danger of premature deep and unsystematic interpretations, i.e., before resolution of the character resistance.

Up to the time of his death in 1957 Reich had many followers who practiced his theories of orgone or vegetotherapy in the United States. He established an "Orgone Institute" and set up his own press, the Orgone Institute Press, in New York. He had an estate in Rangeley, Maine, where he directed the activities of the Orgone Institute and the Wilhelm Reich Foundation, publishing the *Orgone-Energy Bulletin*, the *Annals of the Orgone Institute*. The sale of his orgone box or accumulator brought him into conflict with the United States government. This and his subsequent death dealt a severe blow to his followers.

Although Reich's later therapeutic innovations have failed to gain acceptance, his earlier contributions to psychoanalytic theory and technique in regard to ego psychology and the influence of cultural forces on character development have proved to be of considerable value.

8.6 JULES H. MASSERMAN

SIMON H. NAGLER, M.D.

Introduction

Biographical data. Jules H. Masserman, originator of the biodynamic theory of behavior and prominent psychiatrist, psychoanalyst, and experimentalist, received his training in psychobiology under Adolf Meyer, and in psychoanalysis under Franz Alexander. Since 1946 he has taught at Northwestern University, where he now holds the appointment of Professor of Neurology and Psychiatry. In 1957, in recognition of his important work on experimental neurosis in cats, dogs, and monkeys, he was elected President of the Society of Biological Psychiatry.

Scientific orientation. Masserman has published two volumes on the principles and practice of dynamic psychiatry in which he has attempted to integrate and synthesize various psychological and physiological concepts of behavior. As a result, the term "biodynamics" (a term generically applied to the branch of physiology concerned with the vital functions of all organisms) has come to represent a unique system of psychoanalytic psychiatry, despite Masserman's disavowal of any intention of establishing a new "school."

In brief, it is Masserman's thesis that animal studies can help to uncover fundamental biodynamic principles of behavior and thus contribute materially to behavioral sciences and psychotherapy. On the basis of his investigations of dynamic psychology and the experimental neuroses, Masserman has formulated four basic biodynamic principles concerning motivation, adaptation, displacement, and conflict. He has attempted to correlate these biodynamic principles with psychoanalytic concepts and to consider their relevance to psychotherapy.

Application of Biodynamic Principles to Personality Theory

Motivation. The principle concerning motivation states that all behavior is stimulated by physiologic needs of varying intensity, such as survival, growth, dominance, procreation, even esthetic creativity, and

is directed toward the satisfaction of these needs. In support of this principle, Masserman has pointed out that Freud recognized the influence of somatic demands on mental functioning, and the operation of an indeterminate number of instincts, other than the libidinal ones. And W. McDougall named two dozen or more instinctual drives.

Experimentally, any physiological need can be utilized to activate behavior. The hunger drive is particularly suitable for experimental purposes and has been shown to be related to sexuality, dominance needs, and herd behavior, to substantiate further the concept of the biological origins of social behavior. In numerous experiments it was demonstrated that no learning takes place without relevant motivation; unless training takes the animal's needs and capacities into account, adaptive, contented behavior cannot be effectively established.

Masserman believes that, if we disregard the formulation of the death instinct, "Freud's categorization of the phases of Eros is essentially biological." Thus, for the most part, biodynamic and psychoanalytic concepts relative to motivation can be reconciled. He admits, however, that our understanding of man's esthetic needs on the basis of instinctual strivings and their sublimation is still inadequate. Similar reservations have also been applied to other correlations of biodynamic and psychoanalytic concepts.

Adaptation. The second principle states that organisms react to and define their environment on the basis of their unique needs, capacities, and experiences; their reaction is not determined by some ultimate reality. In terms of the human organism, this implies that the individual's adaptation to a situation is determined by his own perception of that situation. His reaction is not based on evaluations of the situation by other observers; nor is it based on objective reality. "Reality" is, in fact, highly relative. It is dependent on biodynamic factors unique to the species and the individual, and it is subject to many modifications within this framework, as the result of specific needs, past experiences, and present integrative capacities. Although an individual may appear to behave in complete accordance with social norms, he nonetheless nourishes numerous idiosyncratic attitudes and conceptions of his particular universe. Confusion or conflict between social norms and the individual's idiosyncratic concepts leads to disturbed or neurotic behavior. In this sense, neurosis might be defined as the persistence of behavior patterns which no longer serve an effective adaptive function.

This second principle is readily demonstrated in experiments in which the animals' responses appear to be paradoxical. For example, these experiments showed that monkeys avoid bananas when their odor is associated with an unpleasant experience. On the other hand, the cats studied suffered increasingly severe self-administered shocks in order to obtain the reward of food. This response could be interpreted

as indicating that the goal of "masochistic" behavior is not self-punishment; rather, it is reward seeking. Such investigations point up the value of biodynamic findings for the elucidation and clarification of psychoanalytic formulations.

Displacement. The third biodynamic principle postulates that the blocking of goal-directed behavior leads to altered efforts to achieve the same, or compensatory, objectives. Masserman considers this principle to be in harmony with psychoanalytic formulations. The vicissitudes of the instincts (e.g., reversal, repression, and sublimation), and the defense mechanisms of the ego (such as displacement, condensation, reaction formation, symbolization, and fantasy formation) illustrate the principle of adaptive substitution in the face of frustration.

In animal experimentation such substitutive behavior might take hostile and destructive forms. Nevertheless, it is still directed toward satisfaction of the animal's needs. The optimal environment for such experiments should be sufficiently challenging, but not so frustrating as to lead to deviant behavior. When frustrating obstacles are removed, the organism reverts to normally effective behavior, showing that the effective patterns have only been inhibited, not eliminated.

Many animal experiments in this area also demonstrate the prevalence of dominance hierarchies among groups in search of satisfaction of basic needs. Thus, those organisms which constitute the lower order of a group react to their superiors as if they were barriers to the achievement of need fulfillment. As such, they must be submitted to cooperatively, or eliminated aggressively. It is significant that cooperative as well as parasitic relationships were observed in feeding experiments on an animal level.

Conflict. The fourth principle relates to the all important concept of conflict, that is, the clash of two or more strong motivations, accompanied by increasing tension and anxiety, resulting in maladaptive behavior (as in the neuroses and psychoses). Pavlov and others had induced experimental neurosis in animals by simultaneously presenting positive and negative stimuli which could not be differentiated. Masserman demonstrated that opposing stimuli which were approximately equal in terms of motivational strength would result in conflict which might even lead to persisting disturbance in the behavior of animals. Moreover, this behavior resembles the neurotic anxieties, depressions, and inhibitions which arise in human beings when they are faced with conflicting positive and negative choices.

Masserman produced neurotic behavior in animals by producing conflict between the hunger need and fear by pairing food with an aversive stimulus, such as an electric shock or a toy snake. The degree of neurotic disturbance varied with the urgency of the motivations in conflict, the possibilities of avoidance, the availability of alternate solutions, etc. But the

effects of the conflict were remarkably uniform: they consisted of pervasive anxiety; psychosomatic disturbances in respiratory, genitourinary, and gastrointestinal functioning; phobic behavior; stereotyped compulsive movements; sexual behavioral deviations; withdrawal and hostility; and even regressive behavior, such as abnormal dependency.

Biodynamic Principles and Therapeutic Intervention

The factors which accentuate or reduce neurotic disturbance were investigated experimentally. First, it was demonstrated that those variables which increased the basic conflict or hindered its solution increased the neurotic disturbance, even to the point where it threatened the animal's survival. Secondly, Masserman demonstrated that experimental neurosis was ameliorated by such factors as satisfaction of conflicting needs, removal of the animal from the conflict situation (a procedure analogous to a rest cure or vacation), or forcing a solution to the conflict (e.g., making food particularly attractive to the animal, etc.).

Successful attempts at spontaneous solution of conflict were also observed in these experiments. And these efforts probably parallel the manner in which human beings resolve their problems spontaneously, that is, through reexploration of the problem and discovery that mastery is possible. Indeed, this concept is implicit in the training and education of children to cope with a wide variety of problems to achieve mastery.

In psychotherapy, the protective and permissive atmosphere of the therapeutic situation fosters the patient's self-confidence, which can then be utilized for more successful interpersonal relationships and adaptation. The therapist is perceived as a helpful parent-surrogate with whom the patient can explore and resolve his difficulties. Similarly, it was possible to reeducate neurotic animals through handling by a gentle trainer with whom the animal had previously had positive experiences.

A form of social therapy was investigated as well, in which a neurotic animal was placed in a cage with a well trained, normal animal, which it could observe operating the proper switches to obtain food with impunity. This is analogous to placing a neurotic child in a foster home or residential school, in the hope that he may be favorably affected by his observation of and interaction with normal children.

Masserman and his colleagues also conducted extensive investigations of the effects of organic intervention in the form of drugs, electric convulsive treatments, and neurosurgery on the course of experimental neuroses in animals. It is of clinical interest that the efficacy of neurosurgery in their animals depended less on the site and extent of the lesion than on the preoperative personality and experience of the animal

and the methods used for its postoperative care and rehabilitation.

General considerations. Above and beyond these biodynamic considerations, in his approach to psychotherapy, Masserman stresses what he has termed man's "ur-defenses." These are man's faiths, albeit his delusions. The first of these defenses is man's belief in his immortality and invincibility. Numerous religious systems attest to the fact that, from time immemorial, man has refused to believe in the eventual complete end of his existence. The second ur-defense is his belief in the omnipotence of his servants or helpers—his parents, physicians, clergy, various authority figures, etc. The third faith concerns his confidence in the protective function of society, that is, his belief in man's ultimate concern for his fellow man.

Man needs these faiths to live by and the therapist should not try to abolish them. Instead, Masserman insists, we need only assist the patient "gently to find happier beliefs and more creative applications of them. . . . The best therapist is he who helps troubled men rebuild, largely on their own terms, their faiths in themselves, in their fellow men, and in their selected philosophic or theologic systems."

8.7 EXISTENTIAL PSYCHOANALYSIS

EDITH WEIGERT, M.D.

Introduction

Historical development

Role of philosophy in psychiatry. Psychiatry, more than any other medical specialty, requires elucidation of the philosophical premises which guide the psychiatrist's efforts to understand his patient. According to the psychiatrist-philosopher, Karl Jaspers, this understanding is based on a combination of two main trends of investigation. The first of these, objective cognition, refers to the psychiatrist's efforts to follow the chains of cause and effect from the past into the future and, thereby, to establish diagnosis, prognosis, and plan of therapy. The second trend of investigation, emotionally inspired intuition, or empathy, is defined as the psychiatrist's ability to understand the

patient by identifying with him, by putting himself in the patient's place. Emotional participation or identification with the patient may lead to wishful or fearful falsification, which will lead the psychiatrist astray. Indeed, when carried to extremes, intense involvement may lead to a *folie à deux*. Objective cognition also presents certain pitfalls when the psychiatrist is primarily interested in verifying his premises. The reductive method of analysis illuminates important partial aspects of the patient's personality, but the totality of the subject's integrated existence may escape the analyst.

Contribution of phenomenology. The phenomenologist, Edmund Husserl, has recommended that every scientist detach himself intermittently from his premises, setting aside his system of preconceived ideas, in order to gain a new perspective of the phenomena under observation. Inspired by Husserl, a descriptive phenomenology has emerged to enrich psychiatry, as elaborated in the works of Eugene Minkowski, Ludwig Binswanger, Erwin Strauss, Maurice Merleau-Ponty, and others. Minkowski stated that insanity is nothing more than the exaggeration of the individual's habitual character. The vital impetus toward integration (Bergson's *élan vital*) is reduced in mental illness; the crucial contact with "reality" seems distorted to the observer. In brief, the patient exists in a world of his own, more or less, which cannot be fully shared by people who are oriented to "common sense" standards and values.

Out of the phenomenological philosophy grew the various forms of existential philosophies, or *Dasein* analytic studies, each carrying the imprint of the originator's personality. Martin Heidegger conceived of a new synthesis of idealism and realism. Jean-Paul Sartre's writings are characterized by radical nihilism, atheism, and voluntarism. Karl Jaspers, Max Scheler, Martin Buber, Gabriel Marcel, and Nikolai Berdjaev emphasize humanism and theism, as opposed to naturalism and materialism. Although their views of the world are frequently contradictory, all of these philosophers share in common a desire to bridge the gap between subject and object; therefore, their ideas are of vital concern to the modern psychiatrist.

Cultural influences. The upheaval of two world wars, of revolutions and counter-revolutions, and the threat posed by the development of atomic weapons have destroyed our illusions of a lawful and harmonious cosmos which had previously been accepted as "reality." The absurdity of fate has permeated Western culture and has become an almost universal theme of literature, art, and philosophy. Freud anticipated such developments when he wrote *Future of an Illusion*, in formulating his concept of thanatos, the death instinct, as the counterpart of eros, the life-affirming instinct. But are thanatos and eros instincts? Freud's reformulation of his dual instinct theory would seem to resemble the existential dualism of Sartre's *Being and Nothingness*. Sartre agrees that he has much in

common with Freud, but he also disagrees with him on many issues and has created his own theory of existential analysis.

Theories of Existentialism

Phenomenology and existentialism were introduced into American psychology and psychiatry by Rollo May and his associates. May has characterized Sartre's theory as "a nihilistic, subjectivistic extreme in existentialism which invites misunderstanding." On the other hand, he considers Martin Heidegger the fountainhead of present day existential thought. Heidegger's concept of "being-in-the-world" embraces the inseparable polarity of man and world in the "here-and-now" situation, in which his *Dasein* ("being-there," the field of being which is his existence) aims at authenticity. Being-there implies a concern about being which Heidegger has called "*Sorge*" (care), a concept which encompasses anxiety as well as love. (We are reminded here of Sullivan's definition of love as concern for another as well as concern for one's self.) The anxiety component of *Sorge* (care) stems from the fear of not-being—specifically, the fear of death. Man knows that he is destined to die, but he is inclined to forget this. Heidegger sees the authenticity of being-there in the resolution to accept one's destiny, to accept death as a constantly present possibility.

Paul Tillich, the theological interpreter of existentialism in the United States, has defined authenticity as the "courage to be," despite the threat it presents of non-being. But the constant threat of non-being tended to splinter "care" in the concerns of daily living, and the potentialities of authenticity are squandered. Being-there is translated in the sense of the "man," the German impersonal pronoun which is the equivalent of the English "one." The "man" is not fully present. He is preoccupied with his desire to conform to public opinion, the playing of expected roles, meaningless distractions, and aimless small talk. And these preoccupations give rise to a feeling of "being lost to the world" which arouses anxieties and guilt feelings, because it undermines the experience of freedom and responsibility.

Sartre has evolved more lucid, but often paradoxical, existential formulations. Being, the basis of existence, is an enigma to man; but he can objectify the world of things. He can study and handle the "technical" aspects of the environment, "*Umwelt*." He can deal with his fellow man as an object in the "*Mitwelt*" (being with others). His fellow men become objects of his emotions, desires, and fears. He objectifies them in the processes of cognition and manipulative action. For the "other person," according to Sartre, man is an object. The other self "presents himself, in a certain sense, as the radical negation of my experience, since he is that person for whom I am not subject but object." As a subject, however, man remains elusive, partially shrouded in unawareness.

Consciousness, which Hegel called "unhappy con-

sciousness," splits the subject from the object. The other person can objectify the subject more accurately than the subject himself, who is frequently the victim of self-deception. Nietzsche had stated that every man is most remote to himself. Self-consciousness is experienced as an inner split, a loss of face. The self-conscious person loses his mask before the look (Sartre's "regard") by which the other person objectifies and evaluates him; the esteem of the other person makes the subject's conscience conscious to himself. The subject plays the role that common sense dictates but he does not "experience" the role he plays. When he becomes self-conscious, he is embarrassed, ashamed, guilty, because—in Sartre's words—"he is not what he is and he is what he is not." This paradox interferes with the subject's stable identity.

Man is not the automatically functioning product of nature or of human fabrication, an *en-soi* (in-himself), the passive recipient of fate. He is *pour-soi* (for-himself), a project into the future, transcending the present situation with its contingencies and necessities. Man is thrown into the world, dependent on his heredity, his fellowmen, and his luck. Yet he is forced to be free. His desires and fears force him to choose, to take the risk of participating or not participating in each given situation. And by refusing to make a choice, he indicates that he decided not to decide. His emotionally inspired magic imagination rejects and rebuilds the world into which he is thrown, and therewith he transforms himself. The vertigo of freedom confronts him wittingly or unwittingly with the horror of nothingness. Not only is man afraid of the realistic external dangers of his situation; he is equally frightened by the possibility, arising from his imagination, that he may fail to master the situation. He vacillates between faith and lack of faith in himself. He may choose to avoid the danger by repressing his desire; or he may elect to confront the danger by denying his anxiety. But at the moment when he represses or denies, he is not true to himself; he is in a state of "false faith." Man deceived himself by making himself believe. (Belief, in Sartre's formulations, is always make-believe, because when belief enters man's self-consciousness, he represses his doubts. And when he consciously tries to appear honest, he represses his dishonesty.)

In the situation of erotic intimacy man feels liberated from the anguish of nothingness through the high value of love that confirms his existence. But as soon as he makes himself believe that he loves and is loved, doubt creeps into the love relationship. This doubt makes the other person an object of his desires, threatened by the "frustration of nothingness," and, similarly, he becomes an object to the other person. The love relationship deteriorates into the master-slave relationship described by Hegel. In Sartre's system, human reality is a passion. In the projects of the *pour-soi*, man yearns for God as the source of protection from the anguish of nothingness; or, in his

more solipsistic designs, he tries to be God, a superman, *pour-soi* and *en-soi* at the same time. "Man loses himself as man to give birth to God. But the idea of God is contradictory and we lose ourselves in vain; man is a useless passion."

Theory of Personality Development

Karl Jaspers, Ludwig Binswanger, and Medard Boss have integrated the concepts of existential philosophy into European psychiatry. Victor Frankl has developed a therapeutic approach related to existentialism, called "logo-therapy." These psychiatrists attempt to apply philosophical concepts in evaluating and understanding their patients' personality structure and functioning; thus, their interest is not restricted to the causes of mental illness. The objective study of mental mechanisms and dynamics by the reductive method of psychoanalysis had illuminated the personal history of mental patients. The existential psychiatrists have utilized these methods in pursuing their interest in the subjective experience of the total personality of their patients.

Yet, the total personality is elusive, because it is constantly in the process of becoming, in the process of integrating, disintegrating, and reintegrating, of rejecting and rebuilding its self and its world. Even the brain-damaged person is rebuilding his personality and his world out of fragments of perceptions, emotions, impulses, and memories, driven by the horror of incapacitation, which Kurt Goldstein has characterized as the "catastrophic reaction." The neurotic and, to a greater extent, the psychotic individual are also victims of partial fragmentation of the self and alienation from the world, owing to heredity and/or environmental influences, both past and present.

The basic symptom of all mental illness is a partial withdrawal from the surrounding world into a world of one's own. This trend toward egocentricity, solipsism, or autism can be enriching or impoverishing. The world is enriched by the creative personality, who is able to share his values with others. Being-in-the-world is distorted and alienated in the mentally ill person. The world of the hysteric and the distortions in his bodily functions are transformed by the intensity of his egocentric preoccupations. The world of the obsessive person is regulated by rigid, legalistic rituals intended to exorcise the dangers of decay and dirt, which represent death and destruction. Psychopathological transformations are ascribed to the existentialist psychiatrist's intuitive entrance into the patient's subjective experience. Boss tries to enter also into the subjective experience of the dreamer, whose images impress him as fragmented attempts to transcend a situation of stress. Boss sees, even in the most extreme perversions, the patient's attempt to transcend the defensive walls of egocentricity.

Binswanger, in contrast to Boss, uses Heidegger's concept of care only to refer to the manipulation and organization of things and men in political, economic,

scientific, or ecclesiastical institutions, which are engaged in purposeful action, directed toward the common welfare. But in an institution man remains an object, a cog in the wheel, manipulated by managerial skill into encompassing structures. The will to power is tamed by established hierarchies of law and order. Binswanger distinguishes between such transcendence by objectivation and transcendence through love. Gabriel Marcel calls the basic solidarity of men "intersubjectivity." It manifests itself in Martin Buber's "I-thou relation" of mutuality, which uses verbal and nonverbal communication, not for defensive concealment or anxiety-driven adaptation, domination, and appropriation, but for the liberating revelations of communion. This communion, according to Berdjaew, transforms the "individual" into a "personality" who chooses and grants to the "I" and the "thou" the freedom of optimal development. In each meaningful encounter this spontaneous integration of personality arises unplanned and unpremeditated. In the parent-child relationship, in friendship, in the enthusiasm of erotic union, in marital partnership, and in personal religious experience, personality reveals itself, not only as the boundary of nothingness, but as a potentiality of encompassing communion. Karl Jaspers emphasizes that love, a symbol which loses its value in everyday verbal usage, is not merely an epiphenomenon of sexual libido or a product of mature sublimation. Love is present from the very beginning of existence as a potentiality, initially revealing itself in the cry and smile of the infant. It is present in every stage of development as a possibility for mutuality. However, the psychiatrist is always aware that intersubjectivity can deteriorate into the master-slave relationship that Sartre has described.

According to the existentialist view, the regression to infantile forms of adaptation not only is a sign of psychopathology, but may also imply a search for a new beginning. The child is full of potentialities and "good faith." But if this faith is not confirmed during the process of maturation by relationships of mutuality, existential anxieties and guilt feelings build up walls of defense. The growing child and the adult may then revert to the infantile role in "bad faith," to escape from the freedom of decision and responsibility in the face of frustration and rage. Existential anxieties and guilt feelings alienate and distort these separated individuals and imprison them in an autistic shell surrounded by the horrors of nothingness. At every stage of human development, however, the healing power of love can transcend the anxieties of defensive egocentricity.

In summary, on the one hand, love implies the risk of surrendering self-identity, in the desire to approximate the identity and ideals of the beloved. On the other hand, love enriches lovers through the process of identification by fostering in each a renewed self-esteem of authenticity and mutuality.

Application of Existentialism to Psychotherapy

The psychotherapist may select the orientation that suits him best from the various forms of existential philosophy. He does not force any philosophy on his patient by sermon or subtle persuasion, but, inevitably, he will radiate the philosophy he lives by. He tries to know himself and his world in order to be flexible enough to enter into the world of his patient. There is no reality valid for all. The psychotherapist is aware of his own limitations, and he will know if the world of his patient is too "strange" for him. In that event, he will not be able to establish a bond of solidarity with the patient. Solidarity represents a basic trust in his own potentialities and those of his patient for a meaningful collaboration. This does not mean that the psychotherapist should force himself to develop feelings of empathy, nor can he rely only on his emotionally guided intuition in his attempts to understand his patient.

The existentialist respects the scientific method, although he may regret the development of a "scientism" that deifies science, where traditional deities have been discarded as illusions. Scientific objectivation is the basis of every therapy. We must study the patient's past development if his *Dasein*—his present being—is to be opened to the possibilities of the future. The psychotherapist tries to remove the barriers of illusion which are products of the compulsion to repeat past anxieties and habits of escape.

Existential anxiety manifests itself in numerous variations—in castration anxiety, in anxiety about loss of physical or psychological integrity, in separation anxiety, and in the fear of death, destruction, and helplessness. Such anxieties, and the defenses which are erected against them in the form of autistic withdrawal, persisting symbiosis, or overbearing egocentricity, are reexperienced in the psychotherapeutic encounter, until mutual trust between patient and therapist is established. For example, the Oedipus conflict persists as an egocentric desire for unlimited parental gratification and/or vindictive triumph over the therapist as rival. In the face of the inevitable frustration of these desires, the unresolved Oedipus conflict is reexperienced, with various degrees of anxiety, as an unauthentic protest against destiny.

The psychotherapist need not provoke existential anxieties. The patient who suffers from a traumatic neurosis relives the shock of the trauma in his dreams, although he may have forgotten it in waking life. Similarly, every neurotic patient tends to relive the hell of past anxieties, although he may have built up walls of defensive protection against such anxieties. Nevertheless, the repressed tends to return from repression. The patient would not seek the help of the psychotherapist if he had not begun to doubt the "bad faith" which has motivated his defenses.

The attention of the therapist is directed, therefore, toward the patient's hidden anxieties and guilt feel-

ings, which indicate that the patient seeks to free his thwarted potentialities. The patient should not receive false encouragement or comforting support of his defenses, lest he become a mere object of custodial care. Some patients seek comfort in repetitive accusations of past injustices, e.g., protest against the "schizophrenogenic" parent. The patient may build up an illusion that exploration of the past could magically alter his destiny, but there is no redress for past injustice. Death, evil, and destruction cannot be abolished. As he relives the anguish of annihilation in a raging protest against destiny, the adult discovers that he can tolerate frustration which was too much for the child. The patient may then find another way out of the dead end street of impotent protest, for he has in him the freedom to make new decisions which transcend the nothingness that is implied in every experience of frustration.

Transference presents the possibility of sharing anxieties and the rage of frustration with the therapist, but positive as well as negative transferences provide illusory solutions to unresolved conflicts. This applies to the counter-transference as well, which indicates the degree to which the therapist is affected by the patient's anxieties without facing them squarely. Transferences in Freud's terminology are resistances; Sartre conceives of them as manifestations of bad faith—self-deceptions in the face of challenging frustrations, an escape from the deadening aspects of life through denial or distortion of the present situation with its necessarily frustrating limitations. Every psychotherapeutic encounter is a situation of limitation and stress. Erotic attraction can play a role in fostering empathy and intuition, but eroticism is transcended in a relationship of responsible care. Recognition and expression of rage, anger, and hatred may clear the way for an encounter of solidarity and trust. Out of bad faith the original good faith can be reborn, that is, the patient's trust in life, the source of renewal, and the freedom for authenticity and mutuality.

Existentialism has not introduced new methods into psychotherapy. Its emphasis in the therapeutic en-

counter lies in the transcendence of excessive anxieties. The deepest repressed anxiety is directed against the risk of genuine trust. The care of the therapeutic encounter is not a defense against anxiety; it is neither appropriation nor surrender. This trusting care does not recoil from the limitations of the therapeutic situation but wrestles with its frustrations. And it enables both patient and therapist to endure periods of failure. The therapeutic trust can endow both patient and therapist with a new freedom which allows them to develop their potentialities in meaningful collaboration. Through insight into past and present situations, the patient can be freed to transcend his protesting nihilism in the face of frustrations by making responsible decisions which will transform the future. In liberating the patient, the therapist broadens the horizon of his own understanding and therapeutic creativity.

Chapter 9

Personality Theories Derived from Psychology

9.1 PERSONALITY THEORY DERIVED FROM QUANTITATIVE EXPERIMENT

RAYMOND B. CATTELL, PH.D., D.Sc.

Introduction

Experiment and measurement in scientific theory. The birth of modern science is frequently placed around the year 1600 when Galileo began to apply quantitative methods to mechanical observation. It is recognized that chemistry separated itself from alchemy and entered a new phase of vigorous development when Dalton, Lavoisier, and others began to apply quantitative methods to establish laws in chemistry. Indeed, it is generally accepted today, as Mach has said, that "the aim of science is to find the formulae which express the relations among observed phenomena." By these touchstones, what is the status, as a science, of psychiatry today?

That it lacks the stability of concepts, the maturity, and the practical effectiveness which are characteristic of a developed science based upon quantitative laws and experiment is surely evidenced by the considerable divergencies of theoretical viewpoints represented in this book. However, this is even more apparent in the excessive swings of emphasis in approved practice, e.g., the recent change from psychoanalytic therapy to behavior therapy, and from the predominance of psychoanalytic treatment in private practice to chemotherapy in mental hospitals. Young and uncertain sciences characteristically seek to create the illusion of progress by concentration on rapid movement. As to progress, Eysenck, in an expectedly unpopular (but nevertheless sound) survey (Eysenck, 1960) has pointed out that in this decade psychotherapy has failed to demonstrate that it can bring about recovery at a more rapid rate than would occur spontaneously, without treatment. At this moment no refutation satisfactory to a scientist has been given to the as-

sertion that the number of recoveries due to psychotherapy do not exceed those to be expected from chance. However, to argue this point would serve little purpose. Even more optimistic psychiatrists will, as realistic practitioners, readily admit that present methods of diagnosis, control of treatment, and insights into the necessary tactical steps fall far short of the standards required of a developed science.

The present section takes the position that psychiatry is an applied science. As such, it has elements of artistic skill; but in its essentials it must be based on what the sciences of psychology, physiology, and sociology offer. Among the most recent developments in psychology, those which are most relevant concern the concepts, laws, and predictive powers arising out of the experimental and, especially, the sophisticated quantitative studies which have been conducted in the last 10 years. Psychology, like psychiatry, has never lacked theories; indeed, it has assembled an orchestra of resounding scholarship which enjoys a considerable scientific reputation.

The correlation between the development of a technology and the development of pure theory in science cannot be perfect; but it is also true that impressive technological development cannot occur unless the basic scientific theory possesses real potency. If we use an acid test, as proposed here, clearly our technological capacity to eliminate mental disorder or reeducate delinquent personalities does not provide convincing evidence that we have made more than elementary advances in the basic science of psychology.

Unification of theory and measurement. The twin pillars which psychology offers in its support of the development of psychiatry are personality theory and learning theory. Until 50 years ago, personality theory developed mainly as a result of clinical observation as exemplified by the formulations of Kraepelin, Freud, Jung, and Janet, for example, or was based on what might be called literary and general human observation, as exemplified by the work of William James, McDougall, Allport, Klages, Spranger, and others. The

subsequent quantitative and experimental phase, which is the primary focus of this discussion, initially framed its questions in terms of the theories inherited from the earlier clinical and literary phase. More recently, however, it has built upon a theoretical structure of its own. To date, it has failed to produce scientific laws which can aspire to the scope and elaborateness of the scientific speculations derived from the earlier phase. But, on the other hand, there is every indication that it has constructed a very sound foundation. It is the kind of foundation which will produce definite results, expressed as basic laws and having predictive powers. We can expect these to develop in applied science with increasing rapidity in the next decade.

Multivariate Personality Theory

Preliminary issues. One reason why the "message" from the quantitative, experimental approach has not yet come through as clearly as it might is that the dust of conflict hangs over the area, sustained by a battle between the bivariate and the multivariate schools of experimental design. The former follows the classical plan of experiments in physical science; typically, it deals with one independent and one dependent variable. For example, it manipulates a stimulus and measures a response, trying (and often claiming) to hold all else constant while doing so. Wundt, Pavlov, and Skinner are among the advocates of this method which has been inherited in its entirety by the reflexological school of learning.

The second school of experimental design, favoring the multivariate method, springs from Sir Francis Galton, Spearman, and Thurstone, and it is more concerned with correlational methods and the simultaneous study of measurement of many variables.

Advantages of the multivariate method. The Galton tradition, enriched by the contributions of many mathematical statisticians in the multivariate field, has recently given us remarkably enhanced access, by the electronic computer, to problems which were previously unapproachable. Thus, the multivariate method has two major claims to superiority over the classical bivariate experimental design. First, the multivariate experimentalist can grasp wholes, i.e., complex pattern entities, such as the clinician deals with, whereas the classical experimentalist usually deals with a single atomistic variable, which is often of minor importance and incapable of representing a complex concept. Second, the multivariate method can claim to uncover complex causal relationships without the actual manipulation of people and circumstances which has always been considered essential to classical experiment.

Manipulation in the life sciences has two serious drawbacks. First, it is apt to upset the very phenomena it wishes to study. For example, a dog whose adrenal glands have been dissected out is suffering from something more than the removal of adrenalin from his bloodstream. Secondly, manipulation in the life of human beings of those cardinal emotional attachments which are typically involved in clinical generalizations is practically and ethically impossible. It is primarily for this reason that the experimentalist who understands only bivariate designs has turned increasingly to animal experiments. But, even under the most ideal circumstances, application of conclusions drawn from animal experiments, which do not include cultural concepts or concepts of self, to happenings in the minds of men propels the scientist toward speculative reasoning to a degree which is grotesquely out of keeping with the precision which characterized his animal experimentation.

The three-cornered argument. Clearly, then, the familiar cleavage, noted above, between the clinical observer, on the

one hand, and the laboratory experimentalist, on the other, is not the most important dichotomy in research methodology. Actually, there is a three-cornered argument in progress. Or rather, while it might serve a purpose if it were an argument, actually, it is in danger of becoming a mere regression into three camps which are isolated from each other—clinician, "brass instrument" experimentalist, and multivariate experimentalist. Curiously, in some respects, there is a stronger bond between the clinician and the multivariate experimentalist than there is between the multivariate and the bivariate experimentalists. Both the clinician and the multivariate experimentalist are concerned with seeking generalizations, while keeping the totality of behavior in view, through the formulation of hypotheses which cannot be caught or operationally represented by a single variable. For example, both can handle the concepts of drives, and of such multifaceted personality structures as the psychoanalytic concepts of ego and superego. But in another respect, the multivariate experimentalist has more in common with the bivariate experimentalist than the clinician, in that both the multivariate and the bivariate experimentalists demand that concepts be referable to measurable operations and reproducible experiments, whereas the clinician makes no such claim and is, very often, prepared to proceed without the kind of recorded and statistically treated results which the experimentalist regards as indispensable.

Then the third side of the triangle becomes shorter once again when one realizes that the relatively sophisticated mathematical models and statistical analytical procedures used by the multivariate experimentalist are stronger and more remote from the clinician's training than are the experimental and control groups used in the typical bivariate experiment, despite the fact that the multivariate experimentalist's methods are comparatively simple. One of the unfortunate results of the development of mathematics in the multivariate approach has been that, although the clinician and the multivariate researcher are very close in principle and in their formal modes of reasoning, when the clinician has attempted to carry out an experiment, all too frequently he has reverted to the simple designs of the bivariate methodologist. Since, except for a few brilliant examples, psychiatrists cannot also be mathematicians, the effective interdisciplinary organization of research today requires the multivariate experimentalist to convey to the clinician the emerging structural concepts, but not their detailed mathematical support. His task, then, will be to equip the clinician with measuring instruments which correspond to these concepts. The clinical researcher can use these in all manner of criterion experiments, employing a purely logical comprehension of the dimensions measured rather than a mathematical one. After all, the psychiatrist's unique skills involve the application of these measuring instruments, in conjunction with his ability to communicate with the patient. It is as unreasonable to expect him to exhibit equal competence in every area of the field of mathematical, quantitative behavioral research as it would be to expect the multivariate experimentalist to be able to conduct a psychiatric interview competently.

To be realistic, it will certainly be a long time before the mathematical prediction of behavior reaches such a level of comparative completeness that it no longer requires supplemental data from the human intuitive arts. However, there is every reason to believe that the results and implements of multivariate experimental research can ultimately be made available for intelligent use by those not engaged in the research on their production, and that they will add accuracy to psychiatric procedures. Thus, one can hope that future training in psychiatry will integrate these new concepts. This is certainly a possibility, but it is equally certain that very little has been done as yet to bring this about. Indeed, too many teachers in the field of personality theory still are not facing in the direction from which the advances in integration of diagnostic measurement and theory are most likely to come.

Structural Measurement versus "Psychological Testing"

The preceding discussion emphasized the fact that theory and measurement need to be closely united. But it should be made clear that the quantitative approach to psychological theory involves much more than psychological testing. Psychologists have constructed projective and nonprojective "scales" for thousands of variables, and laboratory workers have measured myriads of described variables. Nor is this surprising, for the number of aspects of behavior susceptible to being measured by a scale and labeled is literally infinite, and there is small chance that even two or three of the finite number of psychologists will choose to think the same variable important. Nevertheless, few of these scales have uncovered anything of theoretical importance, and most lie forgotten in professional journals.

Wherein lies the escape from this triviality of measurement? Certainly, as in any science, important concepts must be established, essential in the sense that they wield more predictive power, and basic in the sense that they can be correlated with more psychological laws than concepts less happily chosen. Even when they are found, they may not incidentally correspond operationally with some single variable: for example, anxiety score does not correspond with counted beads of perspiration upon the brow but may correspond to the average measure of a whole pattern of manifestations. But how are these more vital concepts to be discovered and the choice of variables most suitable for their measurement determined?

Applications of factor analysis. There are essentially two ways in which a science can move toward development of its truly efficacious concepts. One is by the process of conceptual trial and error, in which investigator after investigator pits his brains against the obscurities of nature and tries out concept after concept until one is found which fits the facts better than any other and provides more accurate predictions. The second is to develop a "representative experimental design" in which one samples variables according to some sampling technique and then uses a mathematical method, such as factor analysis, to isolate the comparatively small number of underlying influences responsible for the observed relationships of covariation among the individually measured variables.

In such sciences as physics and chemistry, the former approach has been quite successful, and not unduly arduous or wasteful. The concepts of mass, time, temperature, radiation by wave transmission, valency, etc., were, in general, the survivors of no more than half a dozen alternative hypotheses. But unfortunately, it is a fact of history that psychology has not achieved a comparable degree of success, and students of behavior should realize that they are confronted by quite a different kind of problem, requiring a different method. The number of influences to take into account in deciding whether the home team will win a basketball game, or whether Mrs. Jones will decide to speak to Mrs. Smith at a cocktail party, or whether patient X will try to commit suicide, is of a greater magnitude than the number of influences which affect the orbit of Neptune or the rate of the emission of electrons from a heated filament. Clearly, something more drastic must be done if we are to cut our way through the thickets of primal phenomena in order to reach the significant variables or concepts,

concepts which, at the same time, will not be too numerous to make prediction possible.

It is vital that the reader understand the philosophy and the impact of multivariate experimental methods if he is to grasp its revolutionary implications for behavioral research. Unfortunately, space limitations preclude further development of this theme. Perhaps it is enough if the evaluator of theory realizes that methods now exist, particularly in factor analysis, which, when they are used flexibly with rotation to simple structure, are capable of reducing the multitudes of variables to a limited set of underlying functional unities capable of predicting those variables. However, correlational methods and factor analysis must be employed with the added restrictions of a scientific method, rather than the "bare" postulates of a purely mathematical method. Only then are they capable of isolating underlying structures and influences in complex phenomena. Even those critics who have doubted this have agreed that factor analysis is capable of predicting, i.e., accounting for the variance in large numbers of variables by identifying the variance in a comparatively limited number of intervening or underlying variables.

A simple demonstration of the method was provided by Dickman and Cattell, who made 32 physical and kinetic measurement observations on the behavior of 100 balls; the factor analysis of these 32 variables yielded 4 factors, i.e., weight, diameter of the ball, elasticity coefficient, and the length of the string on which the balls were swung. These are the concepts which the physicist would use in formulas to explain the 32 measurements. The clinician may not be able to spare the time to follow the mathematical argument in detail. Yet, he can be reassured at the common sense level by demonstrations of this kind that through behavioral measurements the method is capable of elucidating the same root influences he perceives clinically as accounting for individual differences in behavior.

Surface and Source Traits

For a hundred years psychiatry has struggled with the opposing views that taxonomic schemes are its main stock in trade, and that "understanding the individual patient" through insight makes diagnostic categories unnecessary and even misleading. Finding that pigeonholing patients in types of syndrome grouping did not immediately provide such insight or reliable criteria with regard to therapeutic indications, many psychiatrists suggested the elimination of diagnostic procedures altogether. Instead, they advocated deeper, direct understanding of the dynamics of each case.

To get the full value from diagnostic approaches, such as those developed by Kraepelin and Bleuler, the real need was to press beyond the concept of gross syndromes to a more sophisticated taxonomic system, rather than to retreat. The statistical, quantitative methodology of multivariate experimentation, described above, provides a means of doing this with the mathematical model concepts which are briefly designated by the terms "surface trait," "source trait," "type," and "process."

Definition. A surface trait is simply a set of behaviors which are observed to go together, to appear together, and to disappear together; as such, it has the form of a simple correlation cluster. A syndrome is one form of surface trait. Computer programs such as Taxonome are capable of rapidly finding such clusters among the observations fed into a computer.

In contrast, the source trait is defined as a simple structure factor, i.e., one of the underlying influences which we have indicated above may be located by factor analysis. As will be seen below, examples of the source traits found by factor analysis generally include intelligence, the primary mental abilities described by Thurstone—*anxiety, surgency, ego strength, and superego strength*—and a number of drive patterns, technically called “*ergs*.” The relation of source to surface traits will be discussed below; essentially, the surface traits are “*heapings up*” of behavior which derive from interactions of underlying source traits.

It may be useful to review the developments in personality theory which have already occurred through the application of the concept of surface and source traits. Typically, the multivariate experimentalist measures approximately 300 people with regard to 80 different manifestations in behavior. He then produces a correlation matrix among these 80 variables and by factor analysis finds the factors, i.e., the source traits, underlying the variables. When he finds, say, a dozen source traits, he is moreover reasonably sure that he is finding patterns which have a high likelihood of replication, as patterns, by others and which will have psychological predictive value.

This empirically derived emergence of structure provides the dependable concepts for the construction of testing devices. Indeed, it provides a statistical psychometric basis for hitting the “*bull’s eye*” of such conceptual targets. Herein lies the vast difference between ordinary “*psychological testing*” and what might be called functional psychological testing. In “*psychological testing*,” one simply constructs scales for *a priori* notions or for quite specific bits of behavior; in contrast, in functional psychological testing, one discovers the structures to be measured first. That is, one unearths the inherent dynamic, temperamental, or ability structures—the source traits—in the human personality and then sets out to devise functional factor tests which will permit the precise measurement of these structures and nothing else. We are now concerned with personality theory built upon experiment with functional measurement.

Factor dimensions. Thirty years of psychometric research in the personality field, using all three possible media of human observation, namely, behavior rating *in situ*; introspective evidence, as in the questionnaire or the consulting room; and objective test evidence by laboratory or performance measurements, have yielded a steadily increasing harvest of new concepts in personality theory with which the psychiatrist needs to become acquainted.

Analyses of rating and self-rating (introspective) data yield much the same concepts, around 20 in number. These source traits were indexed initially as factors “*A*,” “*B*,” “*C*,” “*D*,” etc., in much the same way the vitamin researchers first indexed their vitamin influences. A period of time must elapse between the

simple identification of a behavior pattern as behavior, on the one hand, and its thorough interpretation and understanding, on the other.

Descriptions of source traits. It is reassuring for clinicians to find that the first broad factor found by multivariate experimental psychologists had been observed clinically by Kraepelin, Bleuler, Kretschmer, and others. Kretschmer called it the “*cyclothyme versus schizothyme dimension*.” Every factor must have a convention as to positive direction of score, although mathematically it is a toss up. Thus, at the positive pole we find easy expression of affect, good contact with people, and a tendency toward mood swings. At the opposite pole, we find aloofness and rigidity, together with some dissociation of affect from cognition.

It was pointed out above that, for the most part, factor analytic work is based on observations on normal subjects. Consequently, there is no reason to suppose that intrinsically either the cyclothyme or schizothyme temperament connotes abnormality. Historically, they were merely first seen in their pathological dress, and it is possible that what was seen was in each case a specific disease process superimposed on an essentially normal deviation. Certainly, the expressions of the “*A*” factor pattern within the normal range are sufficiently different from schizophrenic and manic-depressive phenomena to justify a more conservative terminology. Consequently, in normals, the “*A*” factor dimension has been called “*affectothymia versus sizothymia*.” The term *sizothymia* is derived from a Latin root meaning “*flatness*” which is characteristic of the schizothyme temperament (apart from any abnormality). After this first major “*A*” factor, a second source trait, “*B*,” which connotes intelligence, was found to have the greatest influence quantitatively on a random set of behavior variables measured in regard to individual differences. Then, in the third place, comes the ego strength factor, indexed as “*C*,” which has most of the properties assigned to it by the psychoanalyst. Factor “*D*” is a general excitability dimension. Source trait “*E*” is clearly recognizable as a dimension of dominance versus submissiveness which has also been studied in mammals and primates and has been correlated with hormone concentration. The “*F*” factor is called *surgency-desurgency*; at the surgent pole, it seems to be related to creative capacity, which is associated with comparatively little general inhibition, while at the desurgent pole, we see a pattern with many features of what is clinically recognized as depression.

The personality theorist who wants to get a real grasp of this field should study the exact nature, i.e., the magnitudes of factor loadings in various behaviors, of from 15 to 20 source traits until he recognizes them easily and understands their mode of expression fairly thoroughly. Some of the most important source traits are set out in bipolar form in Table

TABLE I
Brief Descriptions of Some Primary Source Traits Found by Factor Analysis^a

Low Score Description	Technical Labels		Standard Symbol	High Score Description
	Low Pole	High Pole		
Reserved, detached, critical, cool	Sizothymia	Affectothymia	A	Outgoing, warmhearted, easygoing, participating
Less intelligent, concrete thinking	Low general mental capacity	Intelligence	B	More intelligent, abstract thinking, bright
Affected by feelings, emotionally less stable, easily upset	Lower ego strength	Higher ego strength	C	Emotionally stable, faces reality, calm
Phlegmatic, relaxed	Low excitability	High excitability	D	Excitable, strident, attention-seeking
Humble, mild, obedient, conforming	Submissiveness	Dominance	E	Assertive, independent, aggressive, stubborn
Sober, prudent, serious, taciturn	Desurgency	Surgency	F	"Happy-go-lucky," heedless, gay, enthusiastic
Expedient, a law to himself, bypasses obligations	Low superego strength	Superego strength	G	Conscientious, persevering, staid, rule-bound
Shy, restrained, diffident, timid	Threctia	Parmia	H	Venturesome, socially bold, uninhibited, spontaneous
Tough-minded, self-reliant, realistic, "no nonsense"	Harria	Premia	I	Tender-minded, dependent, overprotected, sensitive
Trusting, adaptable, free of jealousy, easy to get on with	Alaxia	Protension	L	Suspicious, self-opinionated, hard to fool
Practical, careful, conventional, regulated by external realities, proper	Praxernia	Autia	M	Imaginative, preoccupied with inner urgencies, careless of practical matters, Bohemian
Forthright, natural, artless, sentimental	Artlessness	Shrewdness	N	Shrewd, calculating, worldly, penetrating
Placid, self-assured, confident, serene	Untroubled adequacy	Guilt proneness	O	Apprehensive, worried, depressive, troubled
Conservative, respecting established ideas, tolerant of traditional difficulties	Conservatism	Radicalism	Q ₁	Experimental, critical, liberal, analytical, free thinking
Group-dependent, a "joiner" and sound follower	Group adherence	Self-sufficiency	Q ₂	Self-sufficient, prefers to make decisions, resourceful
Casual, careless of protocol, untidy, follows own urges	Weak self-sentiment	Strong self-sentiment	Q ₃	Controlled, socially precise, self-disciplined, compulsive
Relaxed, tranquil, torpid, unfrustrated	Low ergic tension	High ergic tension	Q ₄	Tense, driven, overwrought, fretful

^a In ratings and questionnaires, and now embodied in the Sixteen Personality Factor Test.

I. For example, he might be particularly interested in the "G" factor of superego strength, which has all the ineluctable "categorical imperativeness" of the Freudian superego and has a special relationship to anxiety. As he studies this factor, he will encounter a number of interesting refinements, e.g., the correlations among factors and the existence of "second order" factors, which will be commented on here only briefly. For instance, some patterns show themselves more obviously in overt behavior ("L data"), whereas others emerge clearly only in the questionnaire and consulting room ("Q data") responses. A "Q" prefix is used for the latter, and prominent among them, in the Sixteen Personality Factor Test (16 P.F. Test) is Q₃, or self sentiment strength. The score on this measures the development of the sentiment developed about the self, which seems to indicate the extent to which the individual's behavior is determined by attitudes which evolve from a consciously precise self-concept.

Finally, the Q₄ factor, called ergic tension, seems to represent the general persisting level of drive frustration in the total drive endowment of the individual. As far as one can judge from its correlations and manifestations, this does not merely indicate undischarged libido level in the Freudian sense, but represents the amount of undischarged drive from sex, pugnacity, and any other ergs which may be encountering some of the frustration which is inevitable in our culture in the personal life of the individual.

Assessment of source traits

Questionnaire versus the objective-analytic battery. Granted that these structures and concepts give precision and potential measurability to some of the older, important parameters which are the basis for our understanding any individual, how is the practitioner to assess them? In part, he will want to do so directly by clinical interview. In "normals," e.g., officer candidates for the Air Force, they have often

been evaluated by careful rating procedures. In administering tests, one can use either questionnaires, or objective, miniature situation performances (the Objective-Analytic Battery, or O-A). The latter is ideal but cumbersome, so that, in all probability, the most convenient way to assess source trait levels in individuals is by a questionnaire, providing the questionnaire can be constructed with sufficient ingenuity to avoid excessive motivational distortion by faking. The Sixteen Personality Factor Test has been used widely in both clinical and occupational situations to evaluate the level of the individual on 16 of the 20 factors which have proved most relevant and most reliable. The test yields 16 scores, each on a 10-point scale. However, the psychologist or social worker who has not received sufficient training in this area should be warned that in assessing personality source traits either by this method or by the Objective-Analytic Battery, he is not dealing with a profile of immutable levels, which he is likely to associate with I.Q. tests or ability measures, but with personality traits which can develop and be modified by life circumstances, psychotherapy, etc. Nevertheless, repeat measurements with these scales at intervals of 1 or more years have shown that when life circumstances remain fairly stable, most of these traits demonstrate considerable stability even from the age of 10 on.

The original factor analyses which showed these patterns in normal adult subjects have been applied in the past 10 years to groups of abnormals, pathological subjects, and also at different ages, specifically, at 12 and 13 years of age, at 11, at 7, and, recently, at 4 and 5 years of age. The evidence produced in the questionnaire type of response clearly indicates that most of these factors have a continuity of form, i.e., of loading pattern, over the whole age range and in groups representing different cultures. Thus, high and low surgency is a recognizable pattern at all age levels which have been investigated to date, as are the affectothyme versus sizothyme temperament dimension, ego strength, and the various other factors. Furthermore, studies performed in Italy, Germany, Japan, India, and Australia have shown that the essential form of these patterns survives cultural translation. Therefore, the evidence accumulated to date supports the view that these functional unities are relatively fundamental dimensions of human personality, which may undergo some modification in expression, with age and cultural changes, but which retain a real continuity. This has been an important consideration in recent years for the planning of developmental studies which will be referred to below.

Essentially parallel findings appear when personality source traits are measured through the objective (performance or laboratory) type of test. There are some interesting modifications, however, due to the difference in the power of the eyepiece, so to speak. Some magnification occurs in questionnaires, so that

"second order factors" in the questionnaire realm (very broad factors which take the form of groupings of primaries) emerge only as first order factors (narrower in the total field) in the objective test realm. For example, the single general anxiety factor which appears in objective laboratory test measures fractionates into an interrelated set of subfactors in the questionnaire (namely, the factors of ego weakness, guilt proneness, tension, etc.).

To summarize: in general, the use of objective test batteries, as exemplified by the Objective-Analytic Battery, eliminates certain of the shortcomings of the questionnaire, such as the question of reliability of response. But they require more time, skill, and apparatus for administration. Consequently, to date, the objective test measurement of personality factors has not been used in clinics or mental hospitals as frequently as have the questionnaire measurement techniques, though more exact work in the future will require them.

Construction of the Theoretical Model

Elaborate personality theories which do not offer, as a basic prerequisite, the ability to measure recognizable trait structures involved in the theory will not get very far. On the other hand, a system which has nothing to offer but a set of traits cannot be considered potentially significant, no matter how these traits describe the natural history of the observed species. It follows, then, that psychology must experiment with models which will account for trait interaction and development, for the role of situations, etc., and which will permit accurate prediction of the outcome of trait combinations and conflicts.

Moreover, this model must have diagnostic validity, and it must be applicable to pathological phenomena, despite the fact that, as pointed out above, at least half the data on which it is based is derived from observations of normal subjects. Obviously, there may be special disease processes described in clinical material which are never manifested in any aspect of normal behavior. This problem will be discussed below. A description of the main model is our first concern. This is called the "intersection model," for it treats any behavioral event as something which can be accounted for only in terms of concepts of personality, of situation, and of ongoing process. Each of these variables is clearly represented by a specific formula.

Intersection model. Any act is considered, as far as personality is concerned, to involve the total personality, i.e., the whole profile of source trait scores. The simplest mathematical way of handling this is to assign various appropriate and experimentally obtained weights to the action of specific traits in each given situation and then simply to add these contributions together to get the total strength of the final response. However, if one suspects that the relation obtaining in nature is more complicated than a linear

one, then the formula may be modified by introducing, for example, products or exponentials among the trait scores. But so far this has not been necessary, and the basic equation in this "intersectional" factor analysis model remains what is sometimes called the linear specification equation. It can be represented for "*k*" traits as follows:

$$a_i = b_{i1}T_1 + b_{i2}T_2 + \dots + b_{ik}T_k \quad (1)$$

where $T_1, T_2 \dots T_k$ are an individual's scores on the traits; a_i is the act as we want to predict, and $b_{i1}, b_{i2} \dots b_{ik}$ are behavioral indices or weights for these traits when they are manifested in the context of the situation "*f*."

Concept of the linear specification equation.

This is a simple linear equation. As explained above, it states that the magnitude of any particular behavior manifestation (a_i), such as a symptom, is determined by a whole set of source traits or factors, here indicated by the letters "A," "B," "C," etc., from Table I above. So far, this is in accordance with good psychiatric principles which postulate that most behavior is multiply determined and is not due to the independent action of any single trait or dynamic need. The weights (or "behavioral indices"), which express the extent to which each of the standard common factors is involved in performance, are determined by experiment, followed by a factor analysis, and can be assigned any values, ranging from +1 to -1. The application of this specification equation can be illustrated by two examples. The first of these is an equation discovered by Pierson and Kelly for the probability of recovery from delinquency in adolescent children. The second is also an empirically derived equation and expresses the success of psychiatric technicians (evaluated in their own institutions) as a function of their personality factor scores on the 16 P.F. test. These may be stated (See Table I for trait identification) as follows:

$$\begin{aligned} \text{Response to treatment} = & .1B - .5C + .3D - .1F + .6G \\ & - .2H + .2I + .2J + .2O - .3Q_2 + .2Q_4 \quad (2) \end{aligned}$$

$$\begin{aligned} \text{Psychiatric success} = & .2A + .5C - .2E + .3G + .3H \\ & - .3M - .2O - .3Q_1 + .3Q_3 - .2Q_4 \quad (3) \end{aligned}$$

It should be noted here that in any actual calculation the values for the source trait scores, which, typically, represent the values on a 10-point scale, based on the "stens" in the test score, always represent the individual scores on these common traits. ("Sten" is an abbreviation of "standard ten," meaning a standard score in which sigma equals 2 and the total range is 1 to 10.) The I.Q., the affectothyme ("A"), and the ego strength ("C") factor measures would be familiar instances of such source trait scores. The T 's in the first equation above are replaced with letters to denote particular source traits in the second and third equations. The meaning of these letters was

given earlier, in Table I. It should be noted that whereas the T values which express the unique qualities of the individual constitute the profile of his trait scores, the values which define the situation in which he stands are represented by the "*b*" values or behavioral indices. And these indices are unique to the particular situation, not an individual. They can be identified only by factoring data which include that situation. These behavioral indices describe the extent to which the given situation evokes certain personality traits. It becomes more evident at this point that we have called our general approach the intersection theory, because it considers the act as the intersection of a multidimensional personality with a multidimensional situation. This, of course, is no figure of speech but refers to an equation for actual computations which can be applied to any related problem. The validity of these modes of representation of the individual and the situation can be tested in other ways as well.

Predictive validity. The theory has a practical, testable application. Thus, the practitioner can take the particular scores of a patient on a test, such as the 16 P.F. Test, or the High School Personality Questionnaire (HSPQ), or the O-A Battery. After entering these figures in a familiar equation (obtained by previous researches) for some important situation, he can make a rough prediction of the patient's response. For example, the psychiatrist might be interested in the way a particular individual will respond to a certain therapeutic treatment; provided general research has been used earlier to establish the behavioral indices for this situation, he will be able to make an estimate that is probably much better than one that could be made from intuition alone. The accuracy of the estimate can, of course, be calculated by finding the magnitude of the multiple correlation obtainable from the given weights.

Some psychometrists have been content to use personality source trait measurements and ability factor measurements in just this way, restricting themselves to purely actuarial statistical methods. But this is not utilizing the resources of the intersectional theory of behavior to their full capacity. Surely, the very characteristic that distinguishes a good psychiatrist or psychologist from an accountant or a computer is his desire to use psychological laws as well as those laws which are merely actuarial and statistical. And here, once again, we encounter a substantial advantage of functional psychological testing over mere psychological testing: if these source traits are the natural structures of personality, which we have every reason to believe them to be, or if they correspond to functional states, such as anxiety, stress, elation-depression, which we know them to be in other cases, then we can project the prediction beyond that which is possible actuarially. We can reason and predict to future dates and different occasions, by adding to the formal calculation (or to an

estimate which is "made in one's head") what we know about the way in which these source traits will change with time and situation, and as a result of other influences.

Modifications in source traits. With this potential capability it becomes important for personality theory to develop, as soon as possible, its repertoire of laws and resources of information about these source traits. One of the obvious and immediate directions of possible research is to find the way in which each source trait changes and develops characteristically with age. When it became known, for example, that the general intelligence factor, as defined by Spearman, grew rapidly in early childhood and reached a definite plateau at about 15 to 16 years of age, rather than at a much later age as generally assumed, then predictions about learning rate and future achievement, etc., began to be made with much greater reliability and insight. In the last few years, as information has accumulated about the life course of several well known personality factors, many psychologists who had sat on the fence too long, and looked askance at "factors" as mere mathematical abstractions, became convinced of their reality. For one sees that each shows a highly characteristic age course, quite different from that which would arise from a mere averaging of any mathematical (but unpsychological) set of subtest scores. For example, when the anxiety factor is scored on the eight subtests found to load it most consistently, we discover that anxiety is high in adolescence, then drops steadily until the age of about 35, after which it stays low until old age, when, apparently, it rises again. The ego strength factor also follows an unstable course in adolescence; thereafter, it continues to rise very slowly and steadily with life experience. The provision of such norms should also help to enhance the psychiatrist's understanding of how far individual cases may be deviating from the normal development.

In the next decade, however, research on intersection theory has many other important things to explore in regard to source traits. Central among these is the relative importance of constitution and environmental learning in determining individual differences. Preliminary research certainly shows great differences among them in this respect. Personality theory could also be pushing ahead to manipulative, bivariate experiments carried out on factor measurements, such as anxiety, ego strength, surgency, and superego strength. Since measures are now available, no factor analysis would be necessary; the aim of such research would be simply to determine, for example, which physiological influences and family learning situations determine levels of these primary structures.

Diagnosis and prognosis by the intersection model. In regard to the establishment of the patterns of functional unities in personality which we call

traits, the contention of the factor analyst is that he really needs no check from clinical, i.e., nonmetric types of observation, although he welcomes the enrichment of meaning given thereby to the bare bones of his framework. For he has rested his case on the most fundamental principle for establishing functional connections in science, namely, what John Stuart Mill called "the principle of joint variation." Thereby causal and other connections can be proven, and thereby it can be shown that certain elements of behavior do in fact go together when examined by more precise methods than are available to the clinician's eye and memory. Consequently, it is not surprising that the factor analytic experimental methods first elucidated some of the major patterns which have been observed clinically, for the clinician is using the same principles but without benefit of a computer. Correlational investigations have confirmed the validity of such concepts as ego strength, a general factor of anxiety, superego strength, schizothyme tendency, ergic tension, etc.

Although the basis of the newer concept is different, more precise, and more verifiable, these new factors have been given the labels by which the vaguer shapes which preceded them have been clinically recognized. For example, there can no longer be any justification for several different views of the exact pattern of ego strength expression, or for conflicting views about whether ego structure is a single pattern or several. These issues can be quickly decided by experiment, and in Cattell's *Personality and Motivation Structure and Measurement*, precise "loadings" are given for the various expressions of ego strength, schizothyme tendency, anxiety, etc. Table II shows, for example, how various introspected and observed anxiety manifestations load the anxiety factor.

Universal Index series. The factor analyst usually uses indices for traits to avoid possibly false connotations in popular labels. For example, in the Universal Index series, U.I. 24 corresponds to the general anxiety factor. After this pattern is tied down, the psychometrist must also show how U.I. 24 measures behave in clinical situations. In this case, the factor behaves exactly as the popular conception of anxiety has always behaved. That is, measurements on the U.I. 24 show that the measurements for neurotics are decidedly higher than they are for normals. They show that under psychotherapy and chemotherapy the score on U.I. 24 is reduced. They show that U.I. 24 measures increase in individuals subjected to anxiety-provoking situations. The exact identification of a measurable behavioral pattern for anxiety, U.I. 24, permits these associations to be demonstrated and, incidentally, also permits more precise research to uncover those physiological variables which are related to anxiety. Understanding of physiological associations has been enhanced since factor analytic separation of the response patterns has shown that a stress reaction pattern exists, now called effort stress. This

TABLE II
Psychiatric Symptoms Expressive of Anxiety
A. Self-Rating^a

Item Number	Correlations with Pure Anxiety Factor			Symptom
	Average of 1 and 2	Re-search 1 (Sample of 90)	Re-search 2 (Sample of 150)	
1	+.40	+.32	+.48	Jumpy, nervous
2	+.39	+.32	+.45	Feel lonely
3	+.38	+.36	+.39	Want to get away from it all
4	+.36	+.29	+.43	Worry
5	+.36	+.32	+.40	Do foolish or clumsy things, say the wrong thing
6	+.36	+.27	+.45	Nervous movements (finger tapping)
7	+.36	+.31	+.41	Feel depressed or despondent
8	+.34	+.36	+.31	Excitable
9	+.34	+.32	+.35	Have silly, groundless fears
10	+.33	+.30	+.36	Have a fatalistic attitude
11	+.31	+.36	+.26	Lack of self-confidence
12	+.31	+.32	+.29	Irritable
13	+.31	+.22	+.39	Heart pounds when excited
14	+.31	+.29	+.32	Easily distracted
15	+.30	+.28	+.32	Day-dream
16	+.30	+.21	+.39	Get confused for certain lengths of time
17	+.30	+.26	+.33	Tense
18	+.29	+.33	+.24	Cry
19	+.28	+.30	+.25	Pulse rapid
20	+.27	+.21	+.32	Easily embarrassed
21	+.26	+.23	+.29	Get cold shivers
22	+.26	+.46	+.05	Moody
23	+.25	+.33	+.17	Have rapid emotional changes (i.e., hate to liking)
24	+.25	+.28	+.22	Can't concentrate
25	+.25	+.24	+.26	Get tired easily

B. Psychiatrist's Ratings

Symptom	Correlations with Pure Anxiety Factor
Irritability	+.42
Anxiety	+.33
Depression	+.32
Phobic behavior	+.22
Sleep disturbances	+.13

resembles and was frequently confused with anxiety before the advent of correlational factor analytic evidence, but it behaves very differently in several ways. For example cholesterol in the blood stream seems to be related positively to effort stress measurements but not to anxiety measurements.

Diagnostic criteria. The difference between the theories developed from multivariate quantitative research and those based on clinical observation does not stop at some variations in emphasis in descriptive patterns, some greater clarity in the separation of dis-

tinct concepts, and the possibility of resolving otherwise unending verbal disputes by reference to quantitative experimental results. It may alter the whole theoretical picture, as has happened through findings on the number and nature of the factors involved in a specific process, e.g., in neurosis. For it would appear that clinical observation has succeeded in locating only the more grossly obvious of these functional unities and that a much larger number must be considered. Whereas Freud believed that "anxiety is the central problem in the neuroses," and many psychoanalysts continue to treat neurosis as if the main problem were to reduce the deviant degree of anxiety, the factor analytic approach, by the intersection model, has identified at least seven primary factors which distinguish diagnosed neurotics from normals beyond the $p < 0.01$ level of significance. According to current tentative labels, these include "C-" (ego weakness), "E-" (submissiveness), "F-" (desurgency), "H-" (threectia), "I+" (premsia), "O+" (guilt proneness), "Q₃-" (inadequate self sentiment development), and "Q₄+" (high undischarged ergic tension level), as presented in Table I.

In the Objective-Analytic Battery, seven factors have also been found which distinguish the neurotics from the normals with the same statistical potency ($p < 0.01$), although they cover a broader area than was measured in the questionnaire. The degree of separation of neurotics and normals which can, in fact, be obtained just by the use of the O-A Battery is shown in Figure 1.

If we examine these factors in terms of their clinical association, we recognize that classical psychoanalysis has designated ego weakness, guilt proneness, and

FIGURE 1. Frequency histogram of the linear discriminant function showing degree of diagnostic separation obtainable for 30 normal and 24 neurotic subjects on objective test personality factors. (From Cattell, R. B. *The Scientific Analysis of Personality*, p. 331. Penguin Books, Baltimore, 1965.)

ergic tension as factors in the neurotic breakdown, but it has said nothing about "H—" factor (threitia), "I+" factor (premsia), or "Q₃—" (deficient self sentiment). The evidence produced by studies of twins is that "H" factor is largely hereditary, and represents a general autonomic sensitivity to threat in the low score direction—hence the name threitia. Presumably, this finding of low "H" in neurotics merely indicates that the individual who is highly susceptible to external threats also reacts excessively to threats from internal forces or impulses. It might be that Freud considered this temperamental component too obvious to state, but in any actual calculation of individual differences in neurosis it cannot be overlooked.

The concept of premsia versus harria ("I" factor), on the other hand, adds an entirely new dimension to the theory of neurosis. This factor is largely environmentally determined, although some association has been shown with blood groups. It appears to represent the extent to which the individual has been brought up in an overindulgent and unrealistic environment, as opposed to a disciplined, more self-restrictive atmosphere. The term premsia is an acronym from "protected emotional sensitivity," and the ratings given to children and adults high on this factor stress sensitivity, plaintiveness, dependence, preference for art and drama over science and mathematics, and a tendency toward "fussiness" in personal relations. In school, these children are rated as attentive to, and dependent upon the teacher, demanding of attention, sensitive to criticism, and unpopular with their peers. An unusually high "I" factor is found in neurotics, drug addicts, alcoholics, and a number of other pathological categories. The question of how this predisposition leads into neurosis must be considered still open to experimental check. But, presumably, the attitudes and patterns of behavior generated by this overprotective and indulgent early environment produce the "neurotic hesitation"—i.e., the inability to make a firm decision either to give up some satisfaction or to accept its consequences fully—which has often been noted as one of the origins of the neurotic's unrealistic perceptions.

It is not too difficult to identify the mechanisms whereby subnormal self sentiment development ("Q₃") becomes associated with neuroticism. Low "Q₃" indicates insufficient shaping of, and attention to a clear cut self sentiment, which would help to direct decisions and actions. It has been shown that individuals low on "Q₃" develop more anxiety, presumably because they get into more unstructured and conflicting situations by reason of lack of guidance from the more decided self-concept present in the high "Q₃" individual. Lack of integration follows because behavior is not referred as readily to a defined self-concept.

Similarly, operational explanations have been put forward for the action of others of the new source traits identified through this experimental approach. Space limitations preclude discussion of these traits here, but the hypotheses they have given rise to have already been put to experimental check in some cases. In the main, within the limits of this section, we are reduced to a bald statement that certain source traits have been found and that certain significant score differences have been found among various pathological groups, which, consequently, have resulted in certain diagnostic potencies for the scales concerned. But, in addition, rich theoretical developments have occurred with respect to these concepts in these last few years which require further validation from measurement and experimental findings.

Some clinicians may justifiably feel that, in terms of stimulating clinical research, the approach of the psychometrists has been an unduly cautious one. More specifically, most experimentalists have been very conservative in speculating about

the nature of these entities. Although there is no question that these functional entities are real, one hesitates to name and theorize about them until additional criterion evidence has appeared. And this evidence has not appeared nearly as rapidly as it should, because of the communication gap between the clinicians on the one hand (who have been inclined, when they take to testing, to use some clinically derived test, regardless of its factorial base in research) and the statisticians on the other. The statisticians, whose skills and realm of action have not included the trial of these tests in clinical situations or the testing of them against psychiatric diagnoses, have in the main constructed factor-pure tests—and then simply left them in the clinician's lap. However, now that these factored scales and batteries have been made available in formal publication, in such instruments as the 16 P.F., the HSPQ, the IPAT Anxiety scale, the various factor depression scales, the Objective Analytic Battery, and the Motivational Analysis Test (MAT), we can certainly anticipate a more rapid accumulation of checks against standard psychiatric diagnostic judgments and evaluations of therapeutic gain. From the theoretical point of view, this will result in a much greater understanding of each functionally unitary source trait, which, though we know it already to be established indubitably as functional unit, lacks definitive interpretation with respect to its relationship to age, family background, neurological associates, and, finally, the degree to which it may be modified by therapeutic procedures.

Therapeutic Guidelines

Any personality theory worthy of the name should have intimate contact with the principles and practice of psychotherapy. The traits connected with functional testing and the general intersection theory do indeed give guidance on the strategy and tactics of the individual therapeutic procedure. But discussion of this relationship will also reveal a gap, namely, in relation to what have been called unique traits.

Combination of source and surface trait measurements. Attention must be focused for a moment on the relationship between surface and source traits. Prior to the advent of basic research in personality structure as implemented by the factor analytic experiment described above, most psychological scales consisted of measurements of surface traits or of attempts to relate behavior to a particular test by a kind of blind empiricism. For example, the Minnesota Multiphasic Personality Index (MMPI) was directed to syndromes (surface traits) which had been recognized previously by the psychiatrist. Thus the test served as an aid in assessing the severity of the symptoms of that syndrome in a given case. Essentially, the Rorschach has had a similar aim: to provide independent evidence as to the severity of a particular syndrome, and thereby help to classify the individual's disorder. Ultimately, a host of clinical psychologists discovered many blind empirical relationships between pathological syndromes and response to ink-blots.

This approach to diagnosis, through "special purpose" tests, is the exact opposite of what we have described here as the goal and orientation of the *general purpose structural* test. In the latter, meaningful structures are found first, and tests are then directed to the elucidation of these concepts. However, a sur-

face trait, such as an MMPI scale may offer, can be as much a natural structure as a source trait which is outlined in the 16 P.F. test, for example. Therefore, some reference must now be made to the possible advantages of insightfully combining surface and source trait measurements in diagnosis. It is denied by psychologists, such as Wiggins, who have examined the MMPI by correlations, that its scales have the homogeneity required by the surface trait definition. But in a clinical sense they may have the homogeneity of correlations with actual psychiatric case syndromes. It was pointed out above that a certain correlation cluster or surface trait (e.g., the severity of a conversion hysteria syndrome) may be created by several fairly different patterns of source traits. This can be illustrated by the two following specification equations, each of which describes a group of anxiety reaction symptoms of the same severity. Thus, the first makes the general statement that, typically, anxiety (a in the equation) is due $-.4$ to ego strength ($+.4$ to ego weakness), $+.5$ to guilt proneness, and $+.5$ to ergic tension (frustrated drive level). Other factors are omitted for simplicity of illustration.

$$a = -.4C + .5O + .5Q_4$$

Let us now take two individuals, J and K , with the following scores on the 16 P.F. test.

	C	O	Q_4
J :	.5	.2	.8
K :	.5	.8	.2

When these values are substituted for " C ," " O ," and " Q_4 ," in the specification equation one gets the following result.

$$a_j = (-.4 \times .5) + (.5 \times .2) + (.5 \times .8) = .3$$

$$a_k = (-.4 \times .5) + (.5 \times .8) + (.5 \times .2) = .3$$

In one case, this high anxiety reaction score of .3 (0 is average) can be ascribed to a higher guilt proneness, and in the other to a greater ergic tension. In general, this illustrates that the same surface trait score (overt symptom level) can be understood in terms of different source trait profile scores. It is the latter which provides the understanding essential for effective therapeutic intervention, and the whole movement of recent years to discount the docketing of cases by surface trait scores rests on this fact. On the other hand, experimental examination of the personality factor profiles of psychiatric patients assigned to a given syndrome group does reveal a certain similarity of profiles. For example, as indicated above, neurotics tend to be low in ego strength and surgency, high in ergic tension (" Q_4 "), high in guilt proneness (" O " factor), and high in premsia (" I " factor). Moreover, this still leaves enough room for individual differences: in one patient the level of overt severity of symptoms (i.e., the surface traits) may be

accounted for by a marked ego weakness and a relatively minor guilt reaction, while in another the test results will show that although the patient's ego strength is not deficient to any conspicuous degree, his reaction is much more severe.

Scores expressed simultaneously in surface and source trait structures should be of great value to the therapist in planning his campaign of therapy for the individual patient. Table III provides the weights necessary to estimate the typical MMPI surface trait scores from the 16 P.F. source traits. Thus the former can be analyzed in terms of the latter. To date, this computational approach has had relatively little impact on psychiatric practice. However, several articles now appear in the literature in which a different prognostic outcome has been established experimentally on the basis of one individual's source traits profile as compared with another's, when the actual syndrome measurement by a surface trait scale (such as the MMPI) has been equally severe in both cases and undistinguishable. This does not mean that surface trait measurement, e.g., the MMPI, should be dropped. The purpose of this discussion is to point up the value of a good two-handed use of surface trait (MMPI) and source trait (16 P.F.) measurements in what has been called psychometric depth analysis. One needs to ascertain as accurately as possible both the severity of the actual symptoms and what combination of source traits is most involved in their production. The typical relationships for general surface-source traits have already been established for the average patient as indicated in Table III.

Knowing the causal nexus in a particular patient, at the level of source trait structure, is of obvious value, from both a theoretical and practical standpoint. It can be illustrated from actual measurements by the work of Pierson and Kelly on young delinquents, referred to above. This study showed that in a group of delinquents whose antisocial behavior (surface trait) was equally severe, those with greater ego strength were less likely to modify their behavior in the foreseeable future. On the other hand, subjects who scored high on " D " factor (excitability) were more likely to return to normal behavior. The obvious conclusion to be drawn here is that high " D " factor may result in antisocial, impulsive, behavior, although there is really no serious dynamic (antisocial tendency) distortion in character structure. On the other hand, if the individual has "settled down" to socially maladjusted behavior and, nevertheless, achieved high ego strength, the reconstruction of his modes of reaction is going to be more difficult, because he has a well formed ego and is experiencing comparatively little anxiety. The theories concerning the treatment of delinquency arising from this quantitative experimental approach, as stated by Pierson and Kelly, have turned out to be quite antithetical to those which were developed on previous purely clinical grounds. Theories based on clinical observation have treated the delinquent essentially as a neurotic who is "acting out." As such, he was considered a candidate for the same therapeutic approach, including the reduction of anxiety. The experimental results which showed that delinquents were actually deficient in anxiety led Pierson to argue, instead, that the first task in therapy is to increase the anxiety level of the delinquent, and his results seem to justify this approach.

Precise practical applications of the intersection model theories will require far more survey research than has yet

TABLE III

Predictions (Average Makeup) of MMPI Surface Trait Scales in terms of 16 P.F. Source Trait Scale Scores with Various Attenuation Corrections

For any row in the figures on 16 P.F. trait measures, the weights (rounded to one decimal) are given to apply to the 16 P.F. source trait scores to get the best estimate of the MMPI surface trait scale. The values in the last four columns are the multiple correlations showing how far the 16 P.F. can be expected to estimate the surface syndromes. For example, psychasthenia and anxiety are pretty well estimated, but hysteria and masculinity-femininity are not. These values are based on studies of a "normal" group of 3 cases and should be taken as tentative until checked against the findings derived from investigation of a mixed group of normal and clinical subjects. $N = 300$.

MMPI Surface Trait Estimates	Weights on 16 P.F. Source Trait Measures																Theoretical Value with Reliability Corrections			Uncor- rected

been accomplished and which focuses on discovering specification equations for a wide variety of pathological behaviors. That is, we need to know which personality source traits are involved, and to what quantitative extent, in response to a wide variety of standard life situations, such as occupation, clinical settings, marriage and the family, etc. This is a very considerable undertaking and can only be accomplished if psychiatrists provide more extensive encouragement in getting systematic measurements than they have to date. Specific theories about the role of particular source traits in certain disorders already exist, but the cautious therapist is not going to feel that he can depend upon them until the necessary measurement relations have been cross-validated by larger samples.

Observation of individual conflicts and measurement of common source traits. This is not the only reason for current difficulties in applying source trait theory. There is also a real theoretical difficulty in reconciling observations of conflicts and fixations which are obviously quite specific and idiosyncratic to the patient, with measures of source traits which are by definition common forms. Is Patient X's symptom formation to be related to a sexual trauma at age 3 or to a low score on the ego strength factor ("C"), and what bearing does the answer to the question have on therapeutic techniques?

When the factor analyst studies individual differences and correlates behavior measures, essentially he is developing concepts of common traits. That is to say, the intelligence, or the anxiety, which he is measuring is considered to have the same typical pattern

for all people, as a measure of mass does for all objects; therefore, he ignores certain variations in form in the individual. He does not ignore them completely, however, for to a great extent the peculiarity of expression visible in one source trait is due to the fact that it is combined in particular measures with some other source trait. For example, in the expression of dominance of an individual rated high on the common dominance trait who is also high on the common measure of anxiety, there will be some measure of anxiety, some qualities of rigidity, etc., which will not be present in the person who scores at the same level on the dominance trait but at a far lower level on the anxiety trait. In short, a great deal of what we recognize as the uniqueness of the individual can be very adequately represented by his unique combination of scores on absolutely common traits.

On the other hand, we must also recognize absolutely unique traits, particularly in the dynamic field and in regard to the patient's interests. For example, the interest of an individual in the house in which he was born, or in the sexual life of his grandmother, are continua on which other people cannot be given any real score. At best, we can say that the rest of humanity has a zero score on this scale—and a scale which is useful to only one person is not very useful. One of the most common causes of misunderstanding between the psychometrician and the psychiatrist, as was evident, for example, in a recent symposium debate at

the American Psychological Association in which Thorne, Cattell, and others participated, is that the psychometrician is rarely concerned with unique traits, and the psychiatrist has not grasped the conceptual distinction between a common trait and a unique trait. It happens that a good deal of clinical work is concerned with the immediate observation of unique traits, and this is apt to obscure the fact that in the long run the psychiatrist may have to give more attention to common traits. For example, initially, the clinician may be interested in the specific dynamic conflicts and personal history fixations indicated above, but his ultimate objective is to raise the level of the common trait of ego strength, and to reduce, say, the level of the common trait of anxiety. Obviously, he must attend to the idiosyncratic and cultural attachments in which a common trait (such as the sex drive or the superego) has become entangled; but his final concern is with a general economics of energy which will produce changes which can be recognized by measurements of the massive common traits.

Parenthetically, there exist potent but costly ways of objectively exploring and measuring individual unique trait structure, dynamic or otherwise, notably, through what has been called "P technique." (P technique repeats a battery of measures on the patient for, say, 100 days; his scores are then correlated over time revealing the functionally unitary factors.) When ways can be found to simplify these research approaches for routine application, one hopes that there will be a more extensive use of measurement in psychiatry in regard to the structure and strength of the unique traits. Meanwhile, psychiatry can go a long way in terms of common traits alone, provided the psychiatrist recognizes that both unique and common patterns exist and that the direct manipulation of the unique trait may frequently contribute to change in the common trait measurement.

Specificity of individual conflicts. In principle, the specificity of conflicts and fixations in the individual patient is no different from the specificity of form of a house. A unique dwelling does not prevent the builder or carpenter from using his knowledge of common materials to construct or manipulate the structure of the house. Similarly, as pointed out above, we can account for much of unique psychological structure in terms of different quantitative combinations of common traits. In the last resort we find attachments, it is true, which are absolutely unique to the individual and his history; the handling of these attachments is discussed below.

Application of Dynamic Calculus to Conflict Measurement

If the universal applicability of mathematical-statistical methods to the discovery of structure, as argued above, is valid, then the dynamic, interest-motivation aspects of personality (which have not yet

been discussed) should also admit of an analysis at least equal in precision to that based on clinical methods. Developments from such research, under the name of the "dynamic calculus," have fully justified these expectations.

The two main devices for dynamic analysis which were developed primarily in the clinical field, namely, free association and hypnotism, have been based mainly on the verbal report of the patient. This is true of the early contributions of the psychometricists as well. For tests of interest, such as the Strong, or the Kuder, and approaches to conflict evaluation through such devices as the ordinary questionnaire, have also depended upon the patient's verbal self-evaluation. It is true that, in principle, the evaluation in free association is at a more sophisticated level than are the self-statements about occupational interests in the Strong Interest Test, for example; but ultimately, both depend upon verbal and self-directed evaluation.

More recently, in projective tests, the psychologist has offered the psychiatrist an avenue to dynamic trait measurement which is somewhat more sophisticated. Unfortunately, it has also proved very unreliable, as numerous studies of the Thematic Apperceptions Test (TAT) and other projective tests, have shown. A fundamentally different approach from all of these began when some 90 different objective devices for measuring motivational strength, ranging from measures of perceptual distortion to ego defense mechanisms, through information and physiological responses, such as blood pressure and galvanic skin reflex, were subjected to factor analysis in order to identify their components. For one cannot assume that all motivational manifestations will have a single underlying factor. Actually, the results show seven types of motivation components which appear regularly, no matter how diverse the content of interest may be. This has permitted the measurement of motivational factors by tests which can themselves be "construct-validated" against the factors. It is from such objective measures that the generalizations which are commonly called the *dynamic calculus* have emerged.

At present, the nature of the seven distinct primary motivational components is not fully understood. One theory considers them to be the contributions to any interest, emanating from the id, the ego, the superego, physiological (autonomic) response, complexes, and certain other sources, that is, the sum total of interest in any response or course of action. For example, wanting to succeed in one's profession is analyzed, by such a battery of tests as the MAT, into relative strengths in these components. However, more recent investigations have shown that for both adults and children the seven components fall into two groups; or, to be precise, they are organized by two second order factors. From their nature these have been called, respectively, the integrated and the unintegrated components in interest. Thus a "U" and an "I"

score can be assigned by the battery to the strength of any interest in any given course of action. Such subtests as autism, perceptual distortion, and galvanic skin reflex are found to contribute to the unintegrated component, while such responses as word association, information, and penetrating perception of jumbled sentences contribute to the integrated component.

Current theory in this area favors the view that the unintegrated component, though not wholly unconscious, corresponds to many manifestations which have been clinically described as emanating from the unconscious and has to do with that component of interest which has never found any "reality testing." On the other hand, the integrated component in the battery corresponds to interest which has been tested out, invested in adjusted performances, educated, and integrated with the self-concept. These two components show relatively little correlation in any individual, but Sweney's work suggests that in general a high magnitude of the unintegrated relative to the integrated component score occurs whenever there is conflict in that particular drive or need area. The validities of these batteries are not yet raised to the same level as those familiar in ability batteries, and their reliabilities are lower, but experiment is broad enough to show that these factor structures exist, and promising beginnings have been made toward their theoretical interpretation.

Being able to measure interest strength by objective tests is, however, only a beginning. The next step is to apply such a battery over a wide array of the typical citizen's life interests, in order to attempt to correlate the grouping and structuring of action-interests.

Dynamic structure factors. Suppose a battery of half a dozen objective subtests (to give a single "intensity of interest" score), applied to about 300 normal subjects, is made for each of about 50 attitudes and interest areas. The 50 widely sampled attitudes, each measured by a score on the total battery, are then correlated. Through factor analysis one then has the basis for discovering empirically the way in which interests are commonly interrelated in our culture. The factor analysis of such matrices has yielded about 20 distinct factors, which we shall call "dynamic structure factors" to differentiate them from the motivational component factors just described. The reader will recall that the motivational component factors are *groupings within measurement devices*, which hold over *all* areas of interest, whereas the dynamic structure factors are statements about the way in which our interests fall into some functional unities.

The main result of the dynamic calculus research, as applied to dynamic structure factors, has been the finding that interest factors are essentially biological drives, on the one hand, and sentiments, or aggregates of interests, acquired by education, about certain objects and institutions, on the other. These two distinct kinds of dynamic structure factors must be taken into account in almost any area in which one works. One consequence of this work has been that the theorizing about the nature of drives in man is no longer on a speculative basis; it is now based upon experimental verification by suitable calculation. This work appears

to have verified the psychoanalytic (rather than the biological) position that there are two distinct sexual needs, which Freud described: one, which is directed toward "object love," is mainly heterosexual in character; the other is narcissistic in character.

On the other hand, this research has not supported the list of drives hypothesized by Murray. In actual fact, among the schemas adopted in various historically important writings, McDougall's analysis is closest to the experimentally based structures. In particular, it disagrees with the Freudian reduction of all drives to merely two or three "instincts." It may be that libido, thanatos, etc., will yet appear as patterns at a higher order of factor analysis, but initially we certainly get no less than 9 or 10 drives, including the 2 sex drives mentioned above, fear, gregariousness, curiosity, parental protective behavior, self-assertiveness, pugnacity, etc., a picture which is more closely akin to what the ethologists have observed in the primates. To avoid confusion with instincts, these new, empirical patterns have been called *ergs* and the measures which have subsequently been set up for them in terms of the objective motivational devices have been called measures of *ergic tension level*.

In terms of the mathematical model, these findings can be brought into exactly the same framework as the general personality source traits. Thus, a particular attitude-interest (i.e., a strength of interest as evidenced by responding with a particular course of action in a particular situation, such as "I want so much to go out with X") can be translated into the specification form as before, namely

$$I_j = b_{j1}E_1 + \dots + b_{jk}E_k + b_{j1M}M_1 + \dots + b_{j1M_p}M_p$$

where I is strength of interest in course of action j ; E_1 to E_k are strengths on k ergs; M_1 to M_p are scores on p sentiments; and the b 's are the usual appropriate behavioral indices, found by correlation, which express the involvement of the drive in the action, etc.

It will be seen that the factoring of objective dynamic measures to reveal these b values amounts to a "quantitative psychoanalysis." By this method we are able to say how much (though still in terms of common traits of *all* people) a given interest derives from certain ergic roots. Some interesting findings have resulted in this field, and, again, several of them confirm psychoanalytic positions. For example, interest in smoking is found to be loaded in sex interest, fitting the oral erotic explanation. Some new insights into the nature of drives (ergs) have also emerged, in that a fair number of aggressive attitudes are found to be more loaded by the fear drive than by a pugnacity or sadistic erg as such.

Clinical research with these instruments (the factored MAT, etc.) and theory construction have only just begun. As indicated above, ergs and sentiments, including self sentiment, can be measured, and equations can be stated in two distinct forms—by the integrated component strength and the unintegrated component strength—and there are many indications that differences in these will have special significance for understanding the dynamic makeup of the individual, notably in regard to conflict.

Conflict. One of the most important propositions arising from the above theorems is that conflict over

a given course of action should be recognizable by the coexistence of positive and negative signs in the specification equation. For example, in equation 4, below, the negative behavioral indices for E_2 and E_4 show that, to follow the interest I_j , one must lose satisfactions on E_2 and E_4 , though gaining on E_1 and E_3 .

$$I_j = .4E_1 - .3E_2 + .5E_3 - .4E_4 \quad (4)$$

$$I_k = .4E_1 + .2E_2 + .3E_3 - .1E_4 \quad (5)$$

Furthermore, the model supposes that the severity of conflict is measurable, in theory, by the magnitude of the amount of canceled (negative) behavioral index variance, relative to the total magnitude loading. Thus, in equation 4, there would be decidedly more conflict than in equation 5, indicating that the interest in equation 4 is an interest which, for most people, involves conflict, whereas the other has presumably developed in a less conflictful atmosphere and situation. (The second equation offers .9(+) to .1(-), whereas the first equation offers only .9(+) to .7(-), a balance of satisfaction of +.8 versus +.2.)

It would also follow from this theory that if we took a broad, representative array of the typical individual's total life interest, determined the amount of conflict in each, and then added the scores for the whole field of self-expression, an individual who showed a high conflict score would be expected to be in a more frustrated and conflictful psychiatric state. In practice, to check this by experimentally determining the values for such a calculation is costly, because the behavioral indices must be determined by a separate experiment on each individual. It requires the use of the factor analytic method called P technique, described above. That is, it is necessary to do a factor analysis of the single individual, by scoring him on a wide array of interests each day, for perhaps 100 days and then correlating the changes in these interests over time and identifying the factors which define the influences behind the day-to-day variation of symptoms. Here, again, it will be observed that, in principle, the multivariate experimentalist is doing something very similar to what the clinician does. The two main differences between them are that the experimenter actually *measures* the changing strength of the symptoms, from day-to-day, and *calculates* covariation to see what is connected with what, instead of forming his judgments about connections on the basis of chance observation and mere intuition. Yet, actually, the multivariate experimentalist has the same goal as the clinician who tries to establish interconnections by observing the covariation of symptoms with the impact of daily events and the clinical interaction of psychiatrist and patient.

A few years ago, J. Williams undertook the monumental task of doing factor analyses on as many as a dozen subjects, each measured daily over months. Six of the subjects were patients in a mental hospital; the remaining six were normal controls. The results of this research clearly supported the theory;

that is, the behavioral indices derived from the specification equations for the psychotics indicated a much higher level of internal conflict, i.e., disagreement of algebraic sign, than did those for the normals. Promising as this theoretical advance is, it may be several years before the methods just described on which it is based can be applied to everyday clinical practice.

Fortunately, the demand for extensive calculation has now been overcome by the computer, so that it would not be impossible for a psychiatrist to hand his measurements to a technician, who could then translate the dynamic structure of an individual patient into quantitative form within the hour. The difficulty lies in collecting the data; it has not proved possible statistically to get clear results after less than about 100 days of repeated measurement. This is a lot of time to devote to one patient, but perhaps before long we can hope that a short cut will be found. The advantage of P technique and its associated diagnostic methods lies not only in the objectivity of the findings and in the fact that it provides an index of total conflict in the way just indicated, but also in its ability to "locate" conflict by measures of severity of conflict in particular areas. Certain valid objections can be anticipated at this point. Obviously it is not enough for the psychiatrist (on the basis of classical psychanalysis, but not behavior therapy) to identify clearly the areas of conflict. The patient must also achieve insight and awareness of his conflicts and their origins. But if the therapist can from an early stage in treatment see more exactly where the tensions lie, surely this will be a great aid to him in bringing the patient to the point of achieving such awareness by the best chosen routes.

Let us summarize briefly the potential advantages of the dynamic calculus theory and measurement. First, they equip the psychiatrist with a set of objective measurements in a field where the psychologist and psychometrist previously had little but loose, projective devices to offer. Second, and more importantly, they offer a theoretical foundation for calculations based on these measurements, to guide diagnostic and therapeutic decisions. Obviously, in general, the dynamic calculus concepts do not differ radically from those which have been presented in a variety of psychiatric theories. That is, they describe a series of drives (redefined with the special properties of ergs), a series of acquired dynamic structures (such as sentiment with regard to parents, to occupation, and, above all, to self), notions of conflict, and integrated attitudes. What is new in dynamic calculus is the possibility it provides for measurement of the properties and the existence of formulas for calculation and prediction in conformity with these concepts. An interesting difference from the traditional psychoanalytic conceptualization appears at certain points, notably in the discovery of two structures regulating morals and manners—the superego and self sentiment—instead of just the superego. This inference is supported by the fact that the self sentiment structure is elicited both through the medium of the questionnaire ("Qs") and through the medium of objective measures of motivation in the MAT. Similarly, these independent instrumentalities agree on the superego factor ("G" in the 16 P.F. test).

Third, the findings derived from application of the dynamic calculus theory leave us less in doubt about the number and nature of ergs (constitutional drives). At present, typically, the dynamic specification equations would also take into account about 8 or 9 sentiment structures, but it would give predominant weight to self sentiment and to the superego among these learned structures. Measurement of ergic tension levels over time enables the psychiatrist to evaluate the patient's progress in terms of whether there is a building up or reduction of tension levels and drives, and the same instruments throw light on development in dynamic structures. At present, the MAT actually measures 10 factors (5 ergs and 5 sentiments); it confines itself to these factors because it is unlikely that clinicians will be prepared to handle a more complex predictive system than 10 variables initially. While the clinical usefulness of these is being explored, research should continue to focus on

the remaining ergs and drives to improve the validity of their measurement.

Space limitations preclude a detailed presentation of the advantages of the dynamic calculus theory. The psychiatrist who is interested in exploring the full possibilities of this theoretical system is referred to the contributions by Bischof, Madsen, and Lindzey. In brief, the theory involves, in addition, the concept of a dynamic lattice, which is a map of the way in which interests within the individual become subordinate to ultimate ergic goals through intermediate subgoals. Factor analysis is only one way of unravelling the structure of this lattice; however it is done, one cannot lose sight of the fact that it is really this lattice which the clinician seeks to understand as he attempts to bring about the individual's readjustment, in terms of those interests and goals which will permit greater satisfaction. Using the model of a lattice enables the psychometrist to avail himself of some of the mathematical treatments applied by electricians to understanding complex electrical circuits, as well as certain propositions in information theory. Another important adjunct of the dynamic calculus is the concept of a series of "dynamic crossroads" at which decisions are made in a necessary, typical sequence. These possibilities are discussed in further detail in the auxiliary reading references cited above.

Additions to the Trait Model: Measurement of Temporary States and Role Effects

The theoretical developments which have resulted from the use of correlational methods to locate functional unities in behavior have succeeded to the degree that experiments have continued to replicate about 20 factors in the general area of personality, and some 10 to 15 in the motivational area, as discussed above. The ultimate aim of research, of course, is to clarify the individual nature of these factors, by relation of them to specific criteria, by plots of the typical life course, by nature-nurture investigations, and by exploration of physiological relationships. However, some 20 years of basic research and much debate and refinement of methods (with existing resources) have been necessary before we reached the point where instruments could be given to the clinician. Consequently, this last phase in which, ideally, hypotheses would be developed about the nature of the factors, according to various clinical criteria, has been belated. Indeed, even while some armchair theorists continue to manufacture alleged unitary traits or concepts and describe their predictive importance before they have even been confirmed as patterns, we have the spectacle of a dozen or more well confirmed and measured factor patterns waiting to be employed and enriched in explanation.

Origins of factor patterns. Since it has become increasingly evident that the desire to interpret these confirmed, constantly reappearing unitary factor patterns is gathering momentum, we should inquire first about the general types of influence which can be expected to produce them. It is clear, from the earlier description of schizothyme temperament, ego strength, ergs, and sentiments, that some appreciable fraction can be considered to correspond to genetic endowments, probably with associated physiological variables and that the pattern of behavior emanates from a gene or genes. For example, it would certainly seem from genetic research that the "H" factor (parmia—a toughness associated with predominance of the parasympathetic over the sympathetic reactivity) in the 16

P.F. test can be so classified, and possibly the "A" factor (the schizothyme temperament) as well. In both instances this interpretation is supported by physiological associations and the fact that they have high nature-nurture ratios (examined in studies of twins). Thus, conceivably, we might look to a temperamental mechanism, such as autonomic, sympathetic high responsiveness as apparently shown in the threctic ("H—") pole of the "H" factor, for several such factors.

On the other hand, it is equally clear from the same initial nature-nurture studies that environmental influences must be largely responsible for other source trait patterns. Consequently, in these, the theorist will look to the family atmosphere, to traumatic experiences, and to associations with particular social institutions such as school and church as sources. Here we are presumably dealing with a set of habits laid down by systematic learning experience, which appear in the same mold for everyone because of some standard social institution, but to different degrees of intensity.

Like some RNA template, it fashions the trait to much the same form in the human molecules exposed to it. To appear as a factor, however, it is necessary that people be exposed to the same experiences and yet adopt the pattern to different degrees. Thus, although the factor pattern we are dealing with in these cases may not correspond to some presently active force but rather to a deposit of learned habit skills representing a force once active, the pattern is still worth scoring as a unitary entity, for it remains descriptively and predictively useful to score all people on the degrees to which they possess it. A well known example of this is what is called the crystallized general ability factor, "G_c," which represents the extent to which intelligence has been channeled into scholastic work and skills and which enables us to define and measure the individual's cognitive apparatus by the traditional "intelligence test," in terms of the typical pattern of verbal and numerical skills which the bright child picks up in our school system.

These explanations do not exhaust the possible theoretical bases for source traits; other more subtle possible origins of discovered factor patterns are discussed elsewhere.

Measurement of states. So far we have assumed that factor patterns represent relatively permanent traits, but at this point we need to ask whether a particular pattern might represent some transient state, such as a state of excitement or of depression, or an adrenergic response. At the outset, the formal mathematical-statistical models included "process." We are now asking how a process (a changing state) would appear in mathematical analysis. Note that when we measure individual differences by testing 300 people at a given hour, we normally catch everyone in a transient mood. It is as if we took a snapshot which captured the deviations of that instant. Consequently, some factors thought to be traits (when we subject them to individual factor analysis) might actually be frozen states.

We are confronted here with complex statistical issues. The usual factor analytic search for structure (across, say, 300 people) is called R technique. Earlier, a different factoring (P technique) was described, where one measures one person across, say, 300 occasions. There is also a differential R technique (dR) in which the 300 people are measured once today and once next week, and their change scores on all the variables are then correlated. From such P and dR technique experiments, we are able to discover how many dimensions of change are necessary to account

for the complex changes in emotional state which human beings experience. When this is done, some nine dimensions have been reasonably confirmed which represent state dimensions, such as anxiety, effort stress response, elation-depression, and general fatigue. Just as batteries can be set up for measuring traits, so collections of performance subtests, identified as highly loading such factors, can be built up into batteries for measuring the level at which an individual stands on a particular state at a given moment.

Thus, a complete description of an individual at a point in time requires not only scores upon a set of coordinates corresponding to the common traits, but also a position in the hyperspace defined by the coordinates for these nine states (and others yet to be discovered). The measurement of relatively pure states which, when combined, describe the complex state of an individual at a given moment has considerable importance for both psychiatric therapy and pharmacology. Previously in ataractic drug research, the beautiful precision on the side of the chemist has been matched by a rather vague evaluation on the part of psychologists with regard to the nature and measurements of the states induced by drugs. Within this new framework, it becomes possible to assign to any drug administered in standard dose, an exact vector describing in terms of states the unique combination of changes which it may produce. It also becomes possible for the therapist to use a state measurement, for example, on anxiety, in much the same way the internist uses a clinical thermometer—to study the patient's changing adaptations in response to various therapeutic measures.

Despite the fact that they are still in a psychometrically rudimentary form, some interesting theories have already begun to emerge in regard to these measures of states. For example, it has been pointed out that the newly acquired ability to differentiate the effort stress state dimension from the anxiety dimension offers a different interpretation of serum cholesterol changes. Scheier's simultaneous measurement of distinct effort stress and anxiety factors has also had some interesting results. For example, the anxiety level of students in relation to examinations was found to be higher 2 or 3 weeks before the examination, and it actually seems to fall during the examination itself, but the effort stress reaction rises as anxiety falls. Studies by Pawlik and others have related these behavioral state measurements to EEG records. And the interesting finding has emerged from other investigations that serum cholinesterase rises in an anxiety state. Work has also begun on motivational states, in terms of particular ergic tensions, as measured by the MAT. This is only in its infancy, though it obviously has considerable potential importance for clinical work.

Role modulation. From the standpoint of a really adequate personality theory, consideration of trait factors alone is ob-

viously not enough. One must consider the transforming effect of the situation as well as the inherent nature of the individual's traits. In the general class of transient states presently under consideration, it is particularly important to include those special transients which we call roles. How are we to know when a given piece of behavior is due to the essential personality, and when it reflects an adopted role? The theoretical model we are discussing handles this by conceiving of role as a dynamic structure in the individual which is provoked only by a particular set of stimuli, which are usually related to social situations. In all probability, such dynamic factors would be organized as facets of the self sentiment, but just how this organization comes about has not been properly investigated experimentally. The theoretical possibility also exists that the role behaviors do not only arise from this single factor, but also evolve from some modulation which it produces in certain personality factors. To illustrate, a policeman out of uniform might respond to a traffic violation according to his personality factor profile. But in uniform, under the same circumstances, a whole set of new habits appears, causing a response to an overall situation, rather than the original focal situation, which, in turn, might lead to an expression of personality which differs from the ordinary specification equation.

Whether we adopt the theory that a simple new role factor intrudes or move to this slightly more complex theory, which has been called the theory of personality modulators, we adopt a model which accounts for both temporary role action and the reaction of the states which we discussed above. (Although it is a technical point, it should be mentioned that role modulator action would be likely to appear as a second order factor among personality factors, and one which will only appear in the analysis of certain types of situations.)

It is still too early to judge the extent to which this "temporary modulation" device in personality theory will prove of practical importance to the psychiatrist. However, the recent factoring of psychiatrist and patient interaction by Rickels points to the existence of a quite substantial role reaction factor which simultaneously affects both patient and the psychiatrist in the interview situation. According to this evidence, certain patients adopt the patient role more completely than others, and their dependent, demanding behavior evokes a more "concerned" reaction from the therapist. This, in turn, affects his rating of the severity of the patient's symptoms, to the extent, as shown by our results, that about as much statistical variance in the ratings of anxiety arises from the intensity of this role factor as from the actual patient differences in anxiety and symptom level as revealed by objective tests. It would seem, therefore, that a personality theory without any model and mode of measurement of temporary states and situation-provoked role effects (i.e., one based only on traits) is unnecessarily crude. At a time when chemotherapy is coming into its own, these additional techniques for locating and measuring state components have their most obvious application in giving precision to our understanding of the psychological effects of pharmacological agents.

Personality Learning Theory and Psychotherapy

Personality learning theory has been distinguished from learning theory because the latter has been based almost entirely on atomistic bits of reflex be-

havior. Eventually, both approaches must merge in a general learning theory, but it would be anything but scientific to assume that reflexology can explain the structural personality phenomena which reflexologists have never studied. Psychoanalysis, to name just one body of opinion, has rejected the claims of reflexology to explain its complex phenomena. From the viewpoint of the intersection theory of personality a noncommittal attitude toward present reflexological learning theory is most appropriate. Meanwhile, intersection theory, working with its well defined and measurable personality and motivation traits, takes the experimental position that personality learning theory must explain changes which have been accurately measured according to these trait dimensions. Two important new models have been introduced for the formulation of laws in these areas: "adjustment path analysis," and the "matrix treatment of multidimensional learning."

Adjustment path analysis. The aim of adjustment path analysis and analytical adjustment theory is to set up a standard paradigm to analyze the possible outcomes from a basic, universal psychological situation. This most elementary situation is one which begins with stimulation of a particular drive in a particular situation. Cattell and Scheier have described this elsewhere in some detail in connection with neurosis; however, such adjustment path analysis theory could apply to any kind of dynamic learning. The paradigm is one of a series of choice points at each of which two or more standard possibilities exist. It is not possible to describe these series of "dynamic crossroads" in detail, but one can easily see that they will include such outcomes as whether or not the drive is frustrated, whether or not the barrier is attacked, and whether or not the barrier is overcome. A decision at one point leads to other possible choice points. Thus, in the event that the barrier is not overcome, the alternative is suppression or repression, or continual nonadjustive behavior. From these possible adjustment paths only a certain combination of choices will eventually terminate in the neurotic end path.

Granted this adjustment path theory assigns certain consequences to certain experimental adjustments, one can proceed to an adjustment analysis theory, in which assumptions are made regarding the effects of particular choices upon the dynamic and general personality structure. Indeed the whole aim of the analytical adjustment theory, which includes these and other concepts, is to provide a framework within which personality learning—and particularly the personality learning that has to do with the acquisition of a neurosis and its resolution by relearning—can be brought to experimental study through quantification.

Thus, this adjustment theory provides a framework of analysis and matrix calculations (described below) which is intended to furnish guidance in research designs and to permit statistical analysis of life record data which can serve as the basis for the formulation of laws about personality factor change in learning. Incidentally, it does not merely assume that exposure to a frustrating, traumatic, repressive, anxiety-provoking, or similar unfavorable experience influences personality, but it maintains that personality may exert a reciprocal influence over the choice of such experiences at the various "chiasms" or dynamic crossroads which the organism encounters in the adjustment process. Admittedly, analytical adjustment theory is only a model which expresses in final form the mass of clinical and other evidence which has been accumulated as to the general manner in which personality and situation interact. But if, as hoped, it should prove an effective model in the gathering and reduction of quantitative data, it will further enhance development

of personality theories which are based upon functionally unitary traits.

Let us examine more closely the way in which personality learning change in these adjustment paths can best be considered. According to the model described above, analytical adjustment theory arises from the conceptual analysis of personality into functionally unitary traits and considers that they interact with the environment. Unlike the reflexological approach, it assumes that any experience produces a multiple change in personality, potentially affecting any and all of the scores in the personality profile. This brings us to consideration of the aspect of analytical adjustment theory which is called path transformation theory, and which introduces, by means of matrix algebra, the concept that the effect of any path in the adjustment path diagram provides a certain total pattern of changes in the personality factor profile.

The contributions to such volumes as the *Kentucky Symposium on Learning Theory and Personality Theory* illustrate only too clearly that attempts by psychologists over the past 20 years to unify learning theory and personality theory have been far from successful, especially from the standpoint of the clinician. The central, but perhaps insufficiently appreciated, reason for this is that most learning theorists have conceived of learning purely in terms of a reflexological and atomistic model. By this we mean reflexology in the classical, Pavlovian sense, not in the sense of punishment and reward for various drive expressions. Some of the latter behavior, by a feat of semantic acrobatics, has been "subsumed" by some reflexologists under reflexology.

There are perhaps two major reasons why reflexological learning theory has also been justifiably rejected in principle by clinicians. First, it deals with changes in highly specific bits of behavioral reflexes, whereas the clinician defines his task as the handling of major dimensions of total personality. Secondly, the type of bivariate, manipulative experiment which learning theory employs most frequently has proven inept in relation to human learning, primarily because, as pointed out earlier, human beings cannot be subjected to sufficiently strong manipulative stimulus situations in the laboratory to bring about noticeable changes in personality. Only life itself provides these situations, and only the clinician has an opportunity to watch their action. Consequently, even when laboratory work is directed to important aspects of personality, rather than the eye blink reflex, or something of that kind, it has failed conspicuously to produce significant laws, and the clinician may rightly suspect that entirely new principles will emerge from adjustment path analysis research.

For here, once more, the technical potency of the multivariate method is revealed, in that it can hope to elicit from actual life behavior, without manipulation, evidence of the causal sequences through which personality is affected by environmental learning. To date, this goal has only produced the statement of a theoretical position, namely, that new and different learning principles remain to be unearthed, for, as yet, virtually no concrete experimental evidence has emerged from this proposal.

Meanwhile, an attempt has been under way for some time to apply the more obvious reflexological principles to relearning in the clinical situation, under the name of behavior therapy. The work of such leaders as Wolpe, Rachman, and Costello has resulted in an impressive array of evidence of removal of symptoms by reflexological extinction methods. As yet, there is no clear indication of what this does to the measurements of functionally unitary traits as such. Provided this approach utilizes a broader concept of learning theory than that stated above, it may well either proceed to greater successes or at least provide clear evidence as to the areas in which it is not succeeding. Definite evidence of that kind would be an advance over any therapeutic technique currently available. It will almost certainly be open to criticism, however, if it is used merely—as it is now being used, for the most part—to remove some specific symptom, such as a phobia to a particular object.

For most clinicians are thoroughly familiar with the phenomenon of one symptom disappearing and another appearing, when there has not been a fundamental change in personality structure. The implication of the theoretical position on personality which runs through this section is that whole source traits must be modified if therapy is to be considered successful. This does not rule out the possibility that the amelioration of a weak ego structure ("C" factor), for example, or the reduction of the general ergic tension level ("Q₄" factor) may be affected by the cumulative effect of a number of highly specific readjustments. But, certainly, any general personality learning theory must operate on the basis of the measurement of source traits as a whole.

Matrix analysis of multidimensional learning.

The matrix analysis that is needed for research expresses the central feature of the intersection theory, in that it brings together personality and situation, each in its multiple dimensionality. On the one hand, we have the natural complexity of life experiences over an interval of time, analyzed according to an adjustment process diagram. On the other, we have the equally complex and composite personality change, over the period of interaction with the situation, expressed and measured as change in profile on the measured source traits. From these two matrices (see Figure 2), the possibility exists of arriving by statistical analysis at an understanding of the specific ef-

fects which particular situations have upon particular source traits. While it is impossible to describe this in detail in this brief space, its general principle will be clear to anyone familiar with matrix algebra from Figure 2.

Let us suppose that there exists, as shown in the figure, a matrix which relates the fate of a particular choice to the change in a particular personality factor. In addition, we have a record of the person's historical associations with such choices. The causal direction, as stated above, is presumed to be both from personality to choice, and from choice to personality. But the two together can, if necessary, be considered simply as an empirical association. The second matrix in Figure 2, which is called a path frequency matrix, aims to express by numbers in the cells the frequency with which particular subjects, p_1 , p_2 , etc., involved in the research, have followed and repeated certain paths of attempted adjustment.

From these two matrices we can, by multiplication, produce a third, as shown, which will indicate the extent to which a certain personality profile is likely to be associated with particular persons, in view of this history.

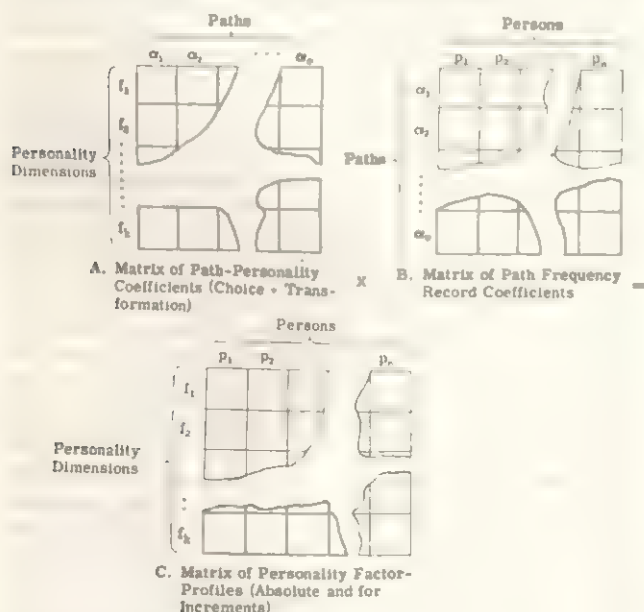

On the whole, this mathematical expression of analytical adjustment theory is nothing more than a means of recognizing that the experience of a particular path of adjustment will simultaneously affect several personality dimensions in characteristic ways, and that different persons will characteristically attempt certain paths of adjustment with characteristic frequency. This could be used, primarily, as a means of calculating what the associations of persons with different personality paths will eventually produce in terms of personality change. However, the calculations and inferences could be made in either direction. If one prefers to make certain assumptions, this calculation can be applied to the solution of unknowns in original personality, to facilitate a desirable set of therapeutic experiences. Thus, the therapist should eventually be able to consider therapy, or various alternatives in therapy, as possible adjustment paths and to work out the effects which these alternative therapies would be likely to have upon the average personality or a given personality. For example, there is some indication that, quite apart from any other effect it may have, group therapy may increase the extroversion of the patient, whereas some other mode of therapy may not do this, and chemotherapy, for example, may reduce anxiety and raise ego strength.

Whereas (in relation to the over-all structural theory outlined here) objective personality measurement and its clinical applications constitute an immediately available practical aid today, applications from the analysis of personality learning are entirely a matter for the future. No experimental use of the design yet exists; consequently, certain technical problems remain to be solved. But it is described as a development which is consistent with the theoretical

CHIEF MATRIX CALCULATIONS IN ANALYTICAL ADJUSTMENT THEORY

1. Calculation of Expected Personality Profiles from Record of Path Frequencies (Experience)

Formula (i) $C = AB$, which can be set out in detail as follows:

2. Calculation of Path Frequency Experience from Personality Profile

Formula (ii) $B = A^{-1}D^{-1}C$, where $D = AA^1$

3. Calculation of General Path-Personality Coefficients from Experimental Data

Formula (iii) $A = CB^1D^{-1}$, where $D = BB^1$

FIGURE 2. Chief matrix calculations in analytical adjustment theory. (From Cattell, R. B., and Scheier, I. H. *The Meaning and Measurement of Neuroticism and Anxiety*, p. 341. Ronald Press, New York, 1961.)

position, and one which would give new power to therapeutic procedure and planning if implemented.

Functional Testing in Clinical Diagnosis and Therapy

There is a widespread illusion on the part of both psychiatrist and psychometrist that the increasingly liberal use of psychological testing by psychiatrists in this generation implies a real use of true quantitatively based theory as here described. Useful though psychological testing practices have been, their application has often had a nonorganic and even patchwork quality. This has been due to the fact that psychiatric theory itself originates from quite different sources from that of test theory. Consequently, tests have tended to be extraneous gadgets (e.g., "special purpose" tests like Rorschach), subordinated as diagnostic instruments to concepts which originated within a different frame of reference.

One can now hope that this relatively ineffective, scientifically unsatisfactory compromise is likely to change radically in the near future, as psychologists trained in functional testing—related to personality theory from experimental origins—become more active in clinical practice and theory. For although much of the new, quantitative theory has turned out to be consistent with earlier clinical impressions (which have thereby been extended and made more precise), it has also produced radically new theory and created a demand that theory and measurement now enter into a truly fruitful relationship.

To get the most out of these possibilities, perhaps the average psychiatrist needs to get over the "inferiority complex"—or, at least, the diffidence—with which he has often approached the technical aspects of psychological testing. In fact, he has no need to apply advanced statistics, such as factor analysis; he must only apply a logical principle which is close to his own, i.e., the concept of a unitary trait. He needs only the simple algebraic formula which sees traits as acting in additive fashion (and linearly) in the specification equation. Similarly, although he uses his knowledge of chemistry to get a general idea of the composition of pharmacological products he prescribes, he would be quite unprepared to understand the steps of synthesis or the abstruse issues of stereochemistry.

Effective use of the proposed measures of anxiety, ego strength, surgency, intelligence, and schizothymia, does, however, require that he comprehend the logical properties of the source trait concepts with which he is dealing and the theoretical setting in which they are embedded. That is, he needs to understand that these source traits derive from factors obtained by correlational methods; that they have a demonstrated functional independence; that they can be considered to interact additively (at least, at first approximation) according to weightings which are decided by the situation in which the action takes place. It would help, too, if he had some idea of second order factors as influences which modify first order factors, and if he would undertake to become as thoroughly familiar with the nature of 20 or so factors, their typical nature-nurture origins and life history, as he is with anatomy or the action of the principle organs in the body.

It has been asserted for some years, partly on the basis of Meehl's interesting work, that six independent bits of information constitute about as much as the human mind can effectively handle in forming a composite judgment. This is

supported in the clinical field by the fact that there is no appreciable increase in predictive power when more than six bits are added to the clinician's basic information. However, as will be pointed out below, in connection with the possible harnessing of computers to clinical work, this conclusion that information on more than six factors is lost must depend upon the way in which clinical work is conducted. Certainly, in terms of how many trait descriptions can be absorbed in psychiatric education, no one is going to make the absurd claim that instruction has to be restricted to half a dozen concepts. Still less, one hopes, will convenience and acceptability be allowed to dictate that nature be simplified to the trinity id, ego, and superego, which is for some the main attraction of Freudian theory. In factor analysis, too, there have been oversimplifications of the real personality factor position which we have tried to describe in a more complete way here. If biochemists can keep 21 amino acids in mind, and chemists can remember more than 100 elements, it is surely no harsh dictum that the psychiatrist should be well aware of the properties of some 20 general personality factors and perhaps an equal number of factors in the motivational structure field. He may not be able to keep the scores on all of them aptly in mind in making a particular diagnosis, but certainly his psychological theory should include them all. For, as mentioned earlier, his quantitative and diagnostic use of them can be augmented and assisted by computational aids in ways we can now discuss, beginning with the choice of tests themselves.

The choice of psychological tests is difficult for the psychologist, and perhaps even more difficult for the psychiatrist, but their bewildering array is brought into some order by the standard Buros' *Mental Measurements Yearbook*, which, like a pharmacopoeia, condenses evaluative research evidence. Actually, the number of tests based on replicated oblique simple structure factor analyses is perhaps 5 per cent of the published total, and if this is one's criterion, the choice is much simplified. However, as pointed out above, in making a measurement of a factor, one has a choice of several media. For example, the superego strength factor ("G" in the 16 P.F. test) can be measured by questionnaire, by objective motivation measure (in the MAT), or by objective tests (including projective, stylistic, and many other varieties of performance) in the O-A. The psychiatrist can also take his choice as to whether he will operate at the primary factor level, as in the factors in the 16 P.F. tests and the HSPQ, or at the second order factor level, using such concepts as anxiety, extroversion, and cortertia. Secondaries can be derived from primary scores by suitable weighting. The second orders enable one to use fewer scores but give rougher results, and for most purposes (especially with clerical or computer aid) primaries are better.

In using factors which psychologists have currently been able to incorporate in their tests, the psychiatrist may well ask whether the methods of investigation have been such as to guarantee an inclusion of most dimensions of theoretical and practical importance. The basing of the first "sweep" on the personality sphere concept has done much to ensure this, but undoubtedly some factors are not yet included in available tests. Research now under way in this area of personality theory is almost certain to add a few new testable dimensions. For example, preliminary work suggests that there are no fewer than eight factors in the area of depression, and a "Pa-

thology Supplement" of several new scales for psychiatric deviations is consequently now being added to the 16 P.F. test to expand its clinical coverage. As pointed out above, there is also some value in measuring certain surface traits (symptom strengths) directly, e.g., by the MMPI, while getting at the general personality source traits by such tests as those just discussed through psychometric depth analysis. There is, of course, room for improvement in all of these tests, but the techniques for progressively moving to more valid factor measurements have been mastered to an increasing extent.

Granted a certain adequacy in source trait measurements themselves, the practice of clinical measurement will also require procedural revisions. The psychiatrist must expect that the time allotted to testing will have to increase. At the present stage of psychometric research, it is simply not possible to cover 20 or 30 personality factor measurements in an hour or two. Even so, the efficiency will be much higher; for testing, as it is traditionally carried out in mental hospitals and clinics today, is definitely wasteful in terms of the number of demonstrably independent pieces of information it yields per hour. Typically, the psychologist spends as much as an hour in getting just one factor, intelligence, and then spends only 5 minutes on some two or three other personality factors each of greater clinical importance than intelligence. Whereas with tests of the pre-factor era he gets 2 dimensions in, say, 80 minutes, the 16 P.F. test, which takes about 40 minutes, gives a score on no fewer than 16 dimensions, including intelligence. Of course, one could not recommend such an extreme condensation as measuring a factor in $2\frac{1}{2}$ minutes by about 12 items. Indeed, it is strongly recommended that no less than 5, and preferably no less than 10 minutes be given to one factor. The compromise presented by the former would result in the practice of using the 80 minutes to give both A and B forms of the 16 P.F. test; the latter would enable the use of the full quota of forms (A, B, C, and D), thus giving about 8 to 10 minutes to each of 16 factors, including intelligence. No adequate reliabilities can be expected unless several equivalent forms are used, for the period of testing is simply too short. Furthermore, there is considerable unnecessary duplication of areas in traditional practices with unfactored tests, whereas any kind of factoring approach, even though it may not be oriented to functional unitary traits, does at least guarantee that the various dimensions are given approximately equal representation in any battery.

Use of the Computer in Clinical Practice

Not infrequently, psychiatrists have been known to complain that training in physical medicine has done them a disservice, because it has set up the model of a definite disease, whereas the pathological phenomena with which they are concerned usually do not fit this model, and, instead, correspond to a "tangle" in the functioning of traits and processes which are, in themselves, as normal as those in any normal individual. There may be instances where a disease process, as abnormal and specific as some germ disease, may play a role in psychiatric illness, e.g., in the organic psychoses. But over the past 20 years, there has been a definite attempt on the part of psychiatrists to emancipate themselves from the incubus of the "sickness" prejudice. They have become disposed to question sharp line disease categories drawn between normality and pathology, and even to regard the behaviors of the psychotic as essentially normal processes, which are merely exaggerated and out of control and context. As pointed out above, the whole of the intersection model and the dynamic calculus theory which

forms part of it are in accord with this view of psychopathology as a problem of disequilibrium and loss of adjustment rather than one of the appearance of specifically malignant disease processes.

In the first place, the factor analytic studies of mental hospital populations, as carried out by Dubin with Cattell some 15 years ago, and with Tatro recently, showed quite early that essentially the same personality dimensions can be found in psychotic as in control groups, even though they stand at significantly different absolute levels of score. Theoretically we would take the position that pathology is either an extreme deviation in particular source traits on a normal continuum, or (probably with greater frequency) an extreme combination of malfunctioning source traits which are not so deviant individually. Empirical evidence which could give a decision on the latter has not been accumulated in sufficient quantity. However, one constantly sees suggested indications. For example, in the paranoid it is not acute anxiety alone, or rigidity alone, but a particular combination of acute anxiety with acute addiction to the reduction of tension by the projective mechanism which seems to characterize this profile. Also, although the source traits of anxiety (U.I. 24) and regression (U.I. 23) are uncorrelated in the general population, they show specific correlation in neurotics. That is, there is not only the repeated evidence, notably from the work of Eysenck and the Maudsley group, but also from Rickels at Philadelphia, and from Cattell's laboratory, that neurotics are highly deviant on each of these factors; there is also evidence that anxiety and regression become highly correlated. Surely, the most promising indication for these findings is that some spiral of interaction between them is setting in. Still another empirical indication that we are dealing with a functional type of disorder, rather than the appearance of a disease due to some foreign agent, lies in the evidence, as yet sparse, but significant, that under therapy the deviant measurements retreat toward normal values. If the process is reversible in this way, and if grades of deviation can be found in our population, surely we are dealing with something which is best described as maladaptive, or having to do with the economics of energy, rather than with some qualitatively distinct disease entity.

In conclusion, it might be said that if a theory properly consists of a model plus a set of laws about its operation, then the intersection theory (and the dynamic calculus concepts) represent only the beginnings of a theory. It is true that the model is clear, and that it fits the facts closely enough to permit a great deal of effective research to be done. For example, it has sufficed to produce experiments which reveal the nature of several source traits, and it has been demonstrated that their interactions fit reasonably closely to the additive model. But all this has occurred too recently for the measurement devices to have been very widely circulated among psychiatrists, so that only a brief early harvest from the use of the concepts and the measurements which arise from them is available as yet. Consequently, the body of laws about the way in which these factors behave is quite fragmentary. Compared with many other theories which are discussed in this book, the present structure, therefore, inevitably lacks several necessary "floors." To see the theory in its proper perspective, one may, on the other hand, claim that its foundation is such as to admit in the long run a far higher and more effective architectonic growth than is possible from the nonexperimental and unquantitative theories. The latter is still preeminent in the field of psychiatry in terms of a sheer count of its adherents, but it is to be hoped that a progressive minority can appreciate what the radical difference of method here means in long term promise. The architectonic growth believed possible will occur most readily if we can bring about the dissolution of the communication barriers between the psychological model theorist and statistician working with the computer in the backroom, and the psychiatrist working with the patient in the

clinic. The writings of such psychiatrists as Werry and Rickels and such psychologists as Cohen and Lorr do much to convey a sense of the gains possible from such communication. What the theoretical development most needs at the present moment is a clear grasp of the particular source trait concepts (temperamental and dynamic) by psychiatrists, and an application of these concepts in relation to the rich clinical criteria to which they alone have ready access and in relation to which new intuitive leads for confirmatory research are needed.

Two important matters have found little or no space in this condensed section: the blending of a scientific theory with psychiatric art, on the one hand, and the specific aids which a quantitative theory can gain from the electronic computer, on the other. If little has been said about the art of psychiatry, and if little space is given to illustration by individual cases here, it is because our primary purpose had to be to provide a highly condensed statement of a still tentative theoretical structure, with very wide ramifications to be followed up. In the application of any theory, however precise and complete, there must, of course, ultimately be art and intuition. However, the theories described here are as different from the most common species of clinical theory in their scientific structure as they are in their suggestions for the art of application. For, essentially, these developments imply that the psychiatrist might advantageously be using his art and intuition at a very different level than that of direct observation and interaction with the patient. Effective interaction at the human level with the patient is, of course, absolutely necessary. But the more developed model here presented means that the psychiatrist can be presented with an array of quantitative evidence of a hitherto unprecedented richness and precision and that he will need to develop his artistic judgment especially in inferring from this evidence what steps are to be taken in his immediate relation with the patient. He is being asked, so to speak, to stand off for a moment from immediate impressions about the patient, and view his makeup and his environmental problem in the perspective of a complex quantitative model.

This will be seen by some as a threat and by others as a remarkable opportunity. The opportunity is inherent in the fact that if the theories are truly quantitative theories, then they should admit of all kinds of actual computations helpful in the diagnostic and therapeutic action with individual patients. This fortunate conjunction of the scientific advent of quantitative theories with the social advent of electronic computers needs to be recognized and seized upon. Here we have an opportunity to inaugurate a very sensitive use of our theoretically required computations, without involving the time and brain power of the psychiatrist in the more routine phases of it. We have been accustomed to an engineer needing mathematics and to a physician getting along without any at all. But as physical medicine and psychological medicine assume more and more the status of advanced sciences, they will necessarily require quantitative methods to be applied to the individual case for their most outstanding feats. Already this is becoming evident in the use of technicians' estimates on hormone concentrations, on basal metabolic rates, and in calculations in physical medicine, in which the doctor either has some calculation carried out for him or makes a rough estimate as he proceeds. Since a human being has a more complicated organization than a bridge or an automobile engine, the psychiatrist of the future is likely to need to have more subtle calculation carried out for him than those which are carried out in engineering.

At a simple level, this impact of our theoretical position can be seen in the use of the specification equation above. It should be possible to store in a computer the weights reached by research for a considerable array of behavioral predictions and prognoses. Profiles can also be stored for an array of patterns needed in diagnosis. However, the psychiatrist may be in need of something more than a service in which the data is sent to the computer and comes back in tomorrow's mail. The psychiatrist is surely almost as much in need as the surgeon is of information and analyses fed back very swiftly. Practical de-

cisions have to be made in therapy in the light of information appearing at the same session, or test results made an hour or two before. Fortunately, the physicists have given their answer to this type of need in the Telstar satellite which potentially is capable of instantly feeding back answers from a considerable bank of information to any location.

Probably, the practical use of such an information bank, in computer calculations of diagnoses and dynamic probabilities, is still 1 or 2 decades away. In recognizing this radical new direction as an important and a likely one, we must also recognize that as an organic outgrowth from quantitative personality theory its effective development must depend on the shaping of theories and effectively predictive laws. What has been described in this section is only a clearing of the foundations, a statement of principles, and some fragmentary beginnings of the superstructure yet to be built. The computer technological development will follow easily enough. The more difficult task is to call psychiatrists and psychologists from their verbal theorizing to the quantitative methods which can give us this superstructure of behavioral science.

9.2 OTHER PSYCHOLOGICAL PERSONALITY THEORIES

RAYMOND B. CATTELL, Ph.D., D.Sc.

GERALD M. MEREDITH, Ph.D.

The aim of this section is to provide an eclectic picture of personality theory derived from "psychological theory," by presenting a survey of all activities in the field. For obvious reasons, such an attempt to integrate so many different levels of methodological sophistication and types of approach can only be made at the sacrifice of internal consistency: our guiding thread is one of historical narrative, and our common focus is on those activities and writings which are concerned with some aspect of personality theory.

Nevertheless, an attempt will be made to present a comprehensive (albeit only one) survey of personality theories derived from all sources, as viewed from the standpoint of the discipline of psychology. No framework for such a wide comparative treatment would be equally suitable for all theories; however, the main categories for this discussion of personality will include the concepts of personality structure, motivation (i.e., dynamics of action), developmental sequences, and environmental determinants (i.e., classification of environmental, as opposed to constitutional forces).

The family resemblance of these various theories, with respect to the concepts within the categories delineated above, would not have been so evident 50 years ago. Furthermore, although it is possible to distinguish constitutional theories, as postulated by Sheldon, or sociological theories, as formulated by Sarbin, it is no longer customary (nor is it actually possible) for a sociologist to deny completely the role of hered-

ity; nor can a constitutional psychologist deny the importance of interpersonal expression or the relationship between personality and social institutions. Emphases differ, but the conceptual framework is becoming increasingly uniform.

Historical Perspective

For the Greeks, a consanguineous relationship existed between man and nature. According to the philosopher Collingwood, a prominent view of nature held that earth, air, fire, and water (the Empedoclean elements) constituted the basic units of composition for all things. The commingling and the separation (synthesis and diacrisis) of these irreducible elements, Hippocrates reasoned, produced different vital fluids (humours), such as phlegm, blood, and black and yellow bile, which constituted the basic determinants of individual temperament and personality types. Thus, in Hippocrates' typology of the sanguine, melancholic, phlegmatic, and choleric personalities, a fusion of physics and psychology may be witnessed. The specific theory of temperament types sought a congruence between personality organization, on the one hand, and distal determinants of the physical world, on the other.

Western man has continued to think in terms of types. In fact, however, while they permit an orderly view of the universe, typologies remove us from specific consideration of individual personality. Typologies may be simple (such as that of Hippocrates), or highly stylized, as seen in the Jungian system, which permutes the conscious-unconscious dimension with the attitudes of introversion-extroversion and the functions of thinking, feeling, sensing, and intuiting. In either case, the "finer grains" of individual differences are sacrificed for broader nomothetic description.

There is some indication of a counter-trend in the contributions of Theophrastus, the founder of literary characterology. In *The Characters*, Theophrastus focused on human traits, as they develop to give color and flavor to the life of the individual. Thus, the slightest nuance of behavior was woven into a composite view of the individual's "life style." In his description of the "Flatterer," for example, Theophrastus described the machinations of the person whose primary life goal is to ingratiate himself with others. For the most part, however, the esthetic tradition of literary characterology has been confined to the writing field and has failed to penetrate the boundaries of academic psychology. (One is reminded here of Lord Dunsany's remark that the excavations of psychologists, like those of road menders, extend for only 2 inches, whereas those of poets, like miners, extend for a mile.)

Consider another relevant contribution from the past. In *The Republic*, Plato conceived of an ideal society consisting of commoners, warriors, and philos-

opher-kings. Within the framework of this global sociology, he further postulated that the individuals who form these ordered classes are motivated by three distinct categories of impulses. The philosopher-king is propelled by strivings for truth and knowledge (for "Good"); the warrior is motivated by courage and strength; the commoner is motivated by desire and baser needs. Thus we have the concept of a sociology sustained by a psychology of individual motivation. On closer study, one finds that Plato went beyond these formulations to link these motivations to somatic structural determinants. Thus, he speculated that the philosopher-king was well developed in the cerebral region (the locus of reason), while the warrior excelled in thoracic development (the locus of courage), and the commoners were characterized by an overly developed visceral zone (the locus of desire; see *Philebus*). In Plato, the stage is set for a theory of man that pays due respect to sociological and biological, as well as psychological determinants.

Preoccupation with change and development within living structure may be traced back to ancient Greece. In Aristotle one finds an interesting notion of process. In reply to the question: "What is an acorn?" Aristotle observed that one must look not only at what something appears to be, but what it tends to become (i.e., being-in-capacity versus being-in-perfection).

The following set of questions, which derive from the intellectual climate of the 3rd century, B.C., may be formulated to assess contemporary theories of personality:

What are the basic units of individual personality organization? The problem of "how" the person is constructed intrapsychically, the proper elements in theory building, constitutes the structural problem.

What are the wants, needs, and desires that propel a man into action? In contemporary psychology, we phrase this issue in terms of instigation, regulation, and maintenance. Essentially, it constitutes the problem of motivation.

What is the relationship between early personality development and personality structure in later life? How does change take place, and how is the person modified over time? Investigations of changes over time (diachronic processes) seek to elucidate developmental sequences.

What is the relationship between environmental events (stimuli) and personality organization? What are the forces that mold and modify behavior in everyday life? This concern with the role of immediate (synchronic) influences on personality focuses on identification of the environmental determinants of behavior.

Within the framework provided by these four broad rubrics (structure, motivation, developmental sequences, and environmental determinants), this section will briefly outline several of the outstanding approaches to contemporary personality theory.

Henry Murray

Personality structure. Henry Murray, who is a psychoanalyst as well as a Professor of Psychology at Harvard University, has adopted Freud's schematic model and formulated his theory around the central structural elements of id, ego, and superego, with some theoretical differences. Thus, for Murray, the id is not only the repository of asocial (and antisocial) impulses; nor does the ego function solely as an inhibitor and repressor. The id is the source of all psychic energy, but this energy derives from instincts which are acceptable both to the self and society, as well as those which are not. To quote Murray, "It seems best to think of the id as consisting of all the basic energies, emotions, and needs (value-vectors) of the personality, some of which are wholly acceptable." Murray conceives of the superego as a cultural implant, which represents an internalized subsystem of "inner" directions which regulate the person's behavior in much the same way external agents once acted. And he includes peer and literary and mythological figures, as well as parents, among the external agents who can contribute to the formation of the superego. Finally, the ego-ideal is related to the superego and represents an idealized picture of the self. It represents the person "at his future best, realizing all his ambitions."

Motivation. Murray has insisted that if we are to achieve adequate understanding of the individual, our investigations must include a sufficiently large number of variables in keeping with the basic complexity of the subject matter under study. And the elaborate theory of needs that he has evolved to explain the problem of motivation supports this viewpoint. Numerous variables have been proposed to permit description of the nature of these motivating "forces." For example, needs may be viscerogenic, that is, linked to organic events, or psychogenic in origin. They may be expressed in overt behavior or revealed in covert phenomena, such as fantasy and dream. Specific needs do not function in isolation within the organism but interact to produce fusion, conflict, prepotency, and subsidization. Finally, Murray fully accepts the pervasive and powerful role of unconscious needs, as postulated by classical psychoanalytic theory. Although Murray's formulations in this area have incorporated some experimental findings, notably those derived from the Thematic Apperception Test (TAT) and from the psychoanalytic research conducted by Rosenzweig and others, basically it rests on clinical observations, almost to the same extent as the purely clinical theories reviewed earlier in this chapter.

Developmental sequences. Consideration of the development of personality over time is of crucial importance in Murray's theory. And in this area, he has elaborated on the psychoanalytic view of the various stages of development, to hypothesize the formulation of five complexes. More specifically, the sequelae of

experiences involving five areas of the body form the nuclei of the claustral, oral, anal, urethral, and castration complexes.

Environmental determinants. Murray has conceptualized two sets of behavioral determinants—press and social-cultural variables. A “press” is defined as the property or attribute of an environmental object or person which facilitates or impedes the individual’s efforts to reach a given goal. These press forces may be objectively discovered (alpha press), or function as subjective, anticipated obstacles in the environment (beta press). Murray draws an interesting distinction between cathexis and sentiment in this connection: Cathexis is the capacity of an environmental object to attract or repel an individual; sentiment refers to the capacity of the individual to be attracted or repelled by these objects. In any event, need and press generally interact and ultimately form a thema, a molar and interactive behavioral unit. Murray and his colleagues have been extremely inventive in their attempts to develop projective devices to uncover the major themas in human personality.

Theodore R. Sarbin

Personality structure. Theodore R. Sarbin, of the University of California at Berkeley, has developed a theory which is multidisciplinary, derived from studies of culture, society, and personality. In addition, the theory is presented within an interactional framework. Personality is conceived of as the integration of role and self. A role is a patterned sequence of learned actions or deeds performed by the individual in interaction with a given situation. The position of the person in a social structure is a function of a set of expectations or acquired anticipatory reactions. That is, an organized system of role expectations is equivalent to a position in the social structure. Varying degrees of organismic involvement accompany various role enactments. For example, level I, which is labeled “role and self differentiations,” is the lowest stage of interactional involvement, while level VI, the highest stage of involvement, is exemplified by ecstasy and *rites de passage*. The second important component of personality, the self, is a cognitive structure which develops as a result of the interaction between the organism and various stimuli (objects and events). The personality word card (PWC), consisting of 200 trait terms, has been developed to quantify dimensions of the self (e.g., self-acceptance versus self-criticism).

Motivation. In early life, the “motivating conditions” which lead to action arise from disturbances in the steady state of the organism. In the neonate, the steady state is maintained by means of chemical equilibrium or homeostasis. In the process of maintaining equilibrium, trace residuals are deposited within the nervous system to form the earliest cognitions. The application of the equilibrium principle from chemical homeostasis to conceptual constancy in Sarbin’s

theory is extended to all cognitive substructures. (This parallels Lecky’s thesis of self-consistency.)

Developmental sequences. The self is an organization of qualities which are un verbalized and un verbalizable at first and are verbalized in part later by gestural devices, such as self-drawing, or linguistic devices, such as naming, the use of adjectives, “I” sentences, etc. The self has its origins in the interaction between two series of events: the maturational series and the personal-social series. The first series, the maturational series, is assumed to remain fairly constant from culture to culture. In contrast, the personal-social series, which is of paramount significance, is characterized by specific modes of interaction at particular times. The self evolves on the basis of the interaction between these series of events through various stages, including the somatic self (S_1), the receptor-effector self (S_2), the primitive constructed self (S_3), the introjecting-extrojecting self (S_4), and, finally, the social self (S_5).

Environmental determinants. The extensive influence of sociological concepts on Sarbin’s theory has led to an emphasis on the social-interactional determinants of personality. Associated with this concept of role as a structural component of personality are hypotheses concerning role expectation. These represent the basic determinants of human behavior. Concomitantly, since personality is defined as the integration of self and role, Sarbin has elaborated on self-role and role-role conflicts as the basis of personality disorganization.

Gardner Murphy

Personality structure. Gardner Murphy, who is Director of Research at the Menninger Clinic, has delineated the basic components of personality to include: (1) physiological dispositions, which stem from genetic and embryological dispositions; (2) canalizations, which are formed early in life; (3) conditioned responses, which are ingrained through repeated reinforcement; and (4) cognitive and perceptual habits which are the joint products of canalization and conditioning. Another structural component of personality is the self, which Murphy defines as “the individual as known to the individual.” The ego, which represents still another component, refers to a system of habits which enhance or defend the self and therefore serve the same function as the mechanisms of defense described in classical psychoanalytic theory. In addition, habits, values, attitudes, percepts, images, and character are cited in Murphy’s theory as structural elements of personality.

Motivation. Murphy has stated that “the ultimate elements in personality structure are the needs or tensions.” A tension is described as a concentration of energy in a particular tissue or group of tissues. Intercommunication among various motives is achieved by the transmission of energy, i.e., tension,

from one region to other regions of the body. As a consequence of this intercommunication, a network of motivation develops. An important feature of Murphy's theory of motivation is his emphasis on sensory and physical needs. For example, the transmission of tensions which have their locus in the sense organs and muscles are the basis for esthetic motivation and for the individual's delight in a variety of esthetic experiences.

Developmental sequences. Murphy contends that there are three distinct stages of personality development. The first stage is one of undifferentiated wholeness (e.g., the mass activity of the newborn); the second stage is marked by a differentiation of functions; the third stage is characterized by a blending of functions into organized, coordinated activity. These stages have been termed globality, differentiation, and integration, respectively.

Environmental determinants. Murphy conceives of the learning process as the interaction between an organism and a specific environment. Through the learning process, connections are formed between needs and responses. These connections are established by means of two processes, canalization and conditioning. The concept of canalization is similar to the psychoanalytic concepts of cathexis and fixation. It is the process by which a motive or "energy pool" finds an outlet by discharging itself in behavior. An important concomitant to early canalizations involving one's own body is the emergence of the concept of self. Since canalization cannot fully explain all learning, Murphy introduces the idea of conditioning to implement this theory. He also recognizes the influences of socialization and the impact of cultural expectations on behavior. Finally, Murphy's emphasis on the immediate stimulus field as a determinant of behavior finds expression in his concept of situationism.

Gordon W. Allport

Personality structure. Possibly more than any other personality theorist, Allport, who is a Professor of Psychology at Harvard, has attempted to construct a personality theory which will take into account the complexity and uniqueness of individual human behavior. And this view is reflected in his definition of personality as the "dynamic organization within the individual of those psychophysical systems that determine his unique adjustments to his environment." The central structural element in Allport's theory is the trait, which may be defined as a determining tendency or a predisposition to act. In reality, no two individuals ever have exactly the same trait, but biological and cultural similarities allow for "a limited number of roughly comparable modes of adjustment." Thus an individual trait stands in opposition to a common trait. A number of other distinctions as well merit consideration, such as trait versus habit, trait versus attitude, and trait versus type. A trait represents the

result of the combination or integration of two or more habits. An attitude is related to a trait; but an attitude is linked to a specific object or referent, while a trait is not. Allport regards a type as a construction that man is fitted to. A person may possess a trait but not a type.

Motivation. On close inspection, one finds a fusion of structure and motivation in Allport's theory. Thus, traits serve not only as a basis of personality description, but also refer to generalized predispositions to behavior. For example, a cardinal trait is "so dominant that there are few activities that cannot be traced directly or indirectly to its influence." In *Becoming*, Allport describes the propriate functions of the personality which form the basis of all attitudes, intentions, and evaluations. This concept of the proprium, which is pivotal in Allport's theory, includes all the aspects of personality that make for inward unity: body image, self-identity, ego enhancement, ego extension, rational agent, self-image, propriate striving, and the knower.

Developmental sequences. Allport's theory minimizes the importance of the individual's history. His goals and strivings provide more important clues for the understanding of an individual than the early child-rearing practices to which he was subjected. To support his theoretical position, Allport has proposed the principle of the functional autonomy of motives. Basically, this principle states that a given activity or form of behavior may become an end or goal in itself, in spite of the fact that it was originally initiated to serve some other purpose. For Allport, the extent to which an individual's motivation pattern is autonomous is a measure of his maturity.

Environmental determinants. Allport's learning theory is an eclectic one. His emphasis on an idiographic approach and the central role accorded the proprium (propriate motives) leaves little room for consideration of environmental influences.

Kurt Lewin

Personality structure. The basic ingredients of personality structure in Lewin's theory are the person and the psychological environment. The life space (L) may be defined as P (the person) + E (the psychological environment). Thus, the life space contains the totality of facts which are capable of determining behavior. Behavior (B) is defined as a function (F) of the life space, i.e., $B = F(L)$. Facts that exist outside and adjacent to the boundary of the life space form a region referred to as the "foreign hull." However, there is two-way communication between the life space and the foreign hull; and this permeability between the two means that facts in the external world may influence the inner world. The person is differentiated into two zones: the perceptual-motor region ($P-M$) and the inner-personal region ($I-P$). The psychological environment (E) is articulated and divided into regions. The characteristics of the psycho-

logical environment are nearness-remoteness, firmness-weakness, and fluidity-rigidity.

Motivation. Lewin subscribes to the theory that each person is a complex energy system. The kind of energy that performs psychological work is called psychical energy. An increase of tension or the release of energy within the *I-P* region is caused by the arousal of need (either biological or quasi biological). This produces disequilibrium within the system. Tensions in the *I-P* system are described in Lewin's theory as vectors or forces operating on the person as he is represented in the life space. These vectors have strength, direction, and point of application and propel the person to a valenced (valued) region of the psychological environment. Tension may be reduced and equilibrium restored either by direct locomotion or by purely imaginary locomotion.

Developmental sequences. Although Lewin does not reject the idea that heredity and maturation play a role in development, the extent of their influence is not elaborated. Rather, he discusses three important concepts in relation to the developmental process, namely, differentiation, boundary properties, and integration. Differentiation refers to an increase in the number of parts of a whole. With age, the psychological environment becomes increasingly differentiated. Boundary properties change in respect to permeability from childhood to adulthood. The subsystems within the adult show greater organizational interdependence than they do in the child. Since development is conceived of as a continuous process, the delineation of fixed, discrete stages is not developed in the Lewinian theory.

Environmental determinants. Lewin did not develop an elaborate learning theory to account for modifications of behavior. Influenced by the Gestalt school, Lewin discusses learning in such terms as cognitive restructuring, differentiation, and organization.

Andras Angyal

Personality structure. Organismic theories of personality, such as proposed by Andras Angyal, are characterized by their emphasis on the unity of functioning of the normal personality. The concept of the biosphere is proposed to describe the holistic entity which includes both the individual and the environment. The biosphere has two poles: the social pole refers to the individual's interpersonal interactions in society; the psychological pole refers to his symbolic functions. An important property of the system is the extent of its rigidity. Plasticity in a system may result in a wide array of functional variations; a rigid system reacts in a uniform and stereotyped manner. Angyal has described three important dimensions of the biosphere, the vertical, the transverse, and the progressive. The vertical dimension refers to a graduated series of actions that lead to a goal; the transverse refers to the coordination of activities into unified behavior units. Since man can form sym-

bolic ideas about himself, the sum total of these perceptions defines the symbolic self. Behavior is a function of a person's self-image.

Motivation. Typical of the organismic penchant for sovereign drive theory, Angyal maintains that system energy comes from the tensions that arise between the social pole and the psychological pole. In this sense, disequilibrium creates the energy necessary for self-expansion. Two phases of self-expansion are autonomy, or movement by the organism to master the environment, and homonomy, which is the submerging of individuality within the social group. These two trends within the biosphere constitute the dynamic elements of Angyal's theory.

Developmental sequences. Angyal has not evolved a theory of learning but relies upon the language of Gestalt psychology. Development of the organism is viewed as a unified process in time. Such theoretical terms as differentiation, reorganization, and shifting are employed to cover the changes that take place in the evolving personality system. Inherent in the biosphere is a central design or pattern that gives coherence to the individual.

Environmental determinants. The major source of environmental determinants is the biospheric occurrence, that is, the dynamic interplay of the environment-organism unit. Experiences that inhibit or impede the total functioning of the organism (e.g., anxiety), are termed bionegative.

Kurt Goldstein

Personality structure. Strongly influenced by the Gestalt school, Kurt Goldstein, who is a psychiatrist, views the organism as an entity that possesses differentiated factors. The concepts of figure and ground, borrowed from the perceptual domain, are used to describe the primary organization of organismic functioning. A figure is defined as any process which emerges to stand out against a background, with properties similar to those described by Rubin. Goldstein differentiates between natural figures, on the one hand, which are functionally embedded in a background consisting of the total organism, and unnatural figures, on the other hand, which are isolated from the total organism and stand out against backgrounds which are also isolated parts of the organism. A figure emerges in response to demands made on the organism, and natural figures are orderly, flexible, and appropriate to the situation. Although there is a potent dynamic emphasis in Goldstein's formulation, he recognizes that many activities of the organism remain relatively constant. To handle this contingency, Goldstein has introduced the concept of constancy (analogous to perceptual constancies in the visual system) to explain the issue of invariance in behavior over changes in the stimulus situation. There is little explication of subsystems within the organism, but Goldstein does draw distinctions with regard to behavior between performances (which are conscious,

willed activities), attitudes (which are moods, feelings, and elements of the "inner life" of the organism), and processes (which are bodily functions).

Motivation. The major concepts employed by Goldstein to deal with the dynamic properties of the organism are (1) the equalization process, or centering of the organism, and (2) self-actualization. In the equalization process, an available energy supply is postulated within the personality which is relatively constant and evenly distributed throughout the system. While the absolute amount of energy available may vary from one person to another, there is an "average" parameter for each individual system. When states of tension (disequilibrium) occur, the organism automatically attempts to return to its "average" state. The compensatory shift to a psychological plumb line defines the centering process and explains the coherence, consistency, and orderliness on the part of the organism faced with a constantly changing environment. The second dynamic property of the organism, self-actualization, is the sovereign motive in the Goldstein theory. The various phenotypic drive states are all manifestations of this single system drive. The fulfillment of any void within the organism is a manifestation of self-actualization. Although this is a universal principle, each person has different innate potentialities, and therefore people strive for self-actualization along different paths.

Developmental sequences. Although the self-actualization concept might suggest various stages of organismic development, Goldstein does not elaborate a developmental sequence, except for some generalities suggesting that behavior becomes more evenly and orderly as the individual matures.

Environmental determinants. Goldstein clearly recognizes the influence and interplay of hereditary and environmental influences. Many of the constancies, for example, are viewed as inborn. The concept of reorganization is used, but no systematic account of the learning process is developed. The effects of environmental determinants are heavily weighted in his concept of "coming to terms" with the environment. The environment produces imbalances in the organismic system; but at the same time it sets the stage which enables the individual to find (or construct) an environment that will "fulfill his destiny." Essentially, coming to terms with the environment means mastering it, for only in this manner can the obstacles to self-actualization be overcome.

Abraham H. Maslow

Personality structure. Maslow, who is a Professor of Psychology at Brandeis University, has developed a theory of personality which focuses on the "psychiatrically healthy man." Thus, in contrast to many personality theories, especially those in the Freudian tradition, which are primarily concerned with pathology, Maslow argues for a reorientation to a concern for a formulation built around the positive view of

man. The structural position of his holistic theory parallels the Gestalt-organismic theories which were described earlier in this section. That is, on the whole, less attention is devoted to structure than to dynamics.

Motivation. Maslow's theory of human motivation assumes that needs are arranged according to a hierarchy of priority or potency. When the needs that have the greatest priority for satisfaction are dealt with, the next stratum of needs emerges and presses for fulfillment. The needs of the individual are arranged on a continuum which ranges from physiological needs (linked to somatic processes) to higher order esthetic needs.

Developmental sequences. Although he does not elaborate a theory of developmental sequences, Maslow recognizes that the young organism is dominated by physiological and tissue needs. As the organism matures, the needs for safety and security become potent. In the optimally adjusted adult, the higher order needs are prepotent.

Environmental determinants. Maslow's studies of self-actualized individuals and his speculations concerning organized societies constitute a unique contribution to personality theory. Maslow believes that man is essentially good. Society may foster antisocial behavior by denying the individual the opportunity to fulfill his inborn needs. However, institutions can be developed which will contribute to self-actualization.

Stimulus-Response Theory

Personality structure. In the tradition of Pavlov, Watson, and Thorndike, *S-R* theory attempts to provide a rigorous, scientific approach to personality. The work of Dollard and Miller typify this orientation, which derives from reinforcement learning theory. Thus, the major structural element in *S-R* theory is the habit, which is a link or association between a stimulus (cue) and a response. The concept of habit replaces the earlier Thorndikian notion of the *S-R* bond.

Motivation. The dynamic component in *S-R* theory is the concept of drive. Generally defined, a drive is any stimulus strong enough to instigate the organism into action. Drives are divided into two categories: primary and secondary. The primary drives are unlearned and innate and are linked to physiological processes. On the other hand, the secondary drives are acquired on the basis of association with primary drive stimulation. The latter account for a large segment of behavior in the socialized adult.

Developmental sequences. Dollard and Miller handle the problem of development and change in terms of a survey of the innate equipment of the organism and the learning process. At birth, the child is equipped with an array of specific reflexes, an innate hierarchy of responses, and a set of primary drives. While these authors have not elaborated a theory of

crucial stages, attention is directed toward the ability to use language and early learning conditions.

Environmental determinants. A great amount of attention is devoted by Dollard and Miller to the four elements of the learning process: drive, cue, response, and reinforcement (i.e., reward). The basic premise of *S-R* theory is that learning only takes place under conditions of drive reduction. To buttress the theory, the concepts of spontaneous recovery, gradient of stimulus, and response generalization are discussed in detail. Recently, Mowrer has extended the boundaries of the original *S-R* position to deal with the broader "crises" in psychiatry and religion as well.

O. Hobart Mowrer

Personality structure. Mowrer, who is on the faculty of the University of Illinois, has developed an original and important theory of personality. However, its originality does not reside in its structural concepts, which are essentially eclectic. In general, Mowrer subscribes to the psychoanalytic structural model of ego, id, and superego, although in contrast to psychoanalysts, such as Freud or Murray, or an experimentalist, such as Cattell, he makes no attempt to specify the number and nature of hypothesized instincts or drives. Rather, his concepts introduce modifications in regard to the dynamic relation of these structural components. Moreover, one must recognize a quality in these structures which differs from the comparatively loose descriptions of the psychoanalysts, for example. More precisely, Mowrer has brought to learning the concepts of habit formation, of the defense mechanisms, and an attempt to translate structures into classical reflex learning theory, couched in Hullian formulations at first, and later in his own. This translation hinges on concepts of internal stimuli and expectation.

Motivation. As indicated, drives are recognized as the primary motivators, but no specific list has been proposed in his scheme. However, he is specific to the degree that he reflects a set of simple biological goals, e.g., hunger, thirst and sex, with which other animal experimenters have been content, and states that social needs (gregariousness), avoidance of loss of "honor," and various relatively intangible nonviscero-genic needs must be considered. Drive-instigated activity, then, is controlled by ego and superego, strengthened in the course of the learning process.

Developmental sequences. Mowrer has outlined four main stages of development, which are not derived from zones of the body as is the libido theory: (1) infantile indulgence, which embodies such psychoanalytic concepts as narcissism and infantile omnipotence; (2) the onset of socialization, beginning with toilet training and similar impositions of social standards; (3) a phase of negativism, involving conflict both with society and with the developing superego; and (4) the outcome of such conflict at adolescence

which may take the form of delinquency, neurosis, or successful adult integration.

Environmental determinants. It is in this area that Mowrer has made his most creative contribution to clinical psychology. Whereas the classical psychoanalytic position sees conflict principally as occurring between ego and id impulses, which lead in practice to attempts to mitigate the repressive acts of a too severe superego, Mowrer believes that the core conflict stems from an alienation from society, and from a superego that is too lenient, rather than too strict.

More precisely, while many clinicians think of the delinquent and the neurotic as deviating from the normal, the former toward excessive, and the latter toward defective impulse expression, Mowrer sees both as "cheating" and as refractory in meeting the role expectations of society and the demands of the superego. The refractory phase in development becomes outright revolt in the delinquent; in the neurotic it is expressed as a defect and results in the repression of superego urges. Translated into the language of learning theory, the neurotic is making a 2-fold error in "punishment avoidance." First, he seeks to hide his misdemeanors, an attempt which is rarely successful; second, he turns his back on guilt, using various defenses, (e.g., escape into hyperactivity, alcoholism, hysteric or compulsive symptoms).

In what Mowrer defines as "integrity therapy," the neurotic is encouraged to confess his deviance and duplicity (which usually refers to his actual behavior, past or present, not merely his "imagined" sins); to recognize that even then society may not accept him again until he has served penance; to satisfy the demands of his superego by social service; and to sever inconsistent ties and seek new alignments. In contrast to the Freudian position, Mowrer has succinctly stated his belief that "the super-ego knows best."

Multivariate Personality Theory

The theories derived from experimental psychology and particularly the application of multivariate statistical procedures are fundamentally different in origin from the theories described above. The concepts and procedures of this approach have been set out in the preceding section of this chapter. Nevertheless, they should be represented in this context as well, however briefly. For one, the presentation of these rather complex hypotheses within the simple framework adopted throughout this section may contribute to their further clarification. Secondly, it will permit comparative evaluation of this rather revolutionary approach to personality theory, as opposed to other, more traditional theoretical systems. There have been relatively few researchers in this complex field, and this discussion rests largely on the work of Cattell and Eysenck, and the less systematic and comprehensive investigations of Baggaley, Burt, Digman, Goldberg, Guilford, Horn, Hundleby, Meredith, Messick,

Pawlik, Peterson, Scheier, Sweney, Warburton, and Wiggins.

Personality structure. Depending on whether the discovered personality factors are described at the primary level (Burt, Cattell, Guilford, Scheier), or only at the second order (Eysenck, Peterson), more or fewer structures will be listed. Typically, however, some 30 factors in questionnaire response and objective tests are recognized as primary personality components which, in turn, give rise to perhaps 6 to 10 higher order components. Some of the primary factors (e.g., ego strength, schizothymia, superego strength) serve to facilitate experimental mental confirmation of clinical theory; others (e.g., cortertia, parmia) proceed to new concepts.

These unitary structures comprise three modalities—abilities, temperament dimensions, and dynamic traits—and have been shown to be determined to varying degrees by heredity and environment. In the dynamic field they proved to be primary drives (i.e., nine of them, including sex, fear, and curiosity); acquired social sentiment structures (to home, to religion, to self); and defense mechanisms.

Because they are simple structure factors, these factors are measurable mathematically on the 16 P.F. test, the M.M.P.I., O-A Batteries, and the Motivation Analysis Test (M.A.T.). The basic theory of their interaction assumes that they are simply summative in action (although speculations regarding complex curvilinear relations are also entertained) so that the magnitude of any particular action or symptom may be accounted for by a specification equation, as follows:

$$\text{Response} = b_1T_1 + b_2T_2 \cdots + b_kT_k$$

where T_1 to T_k are k source traits (factors) with values appropriate for the given individual, and the b 's, or behavioral indices, are peculiar to that response and the situation in which it occurs. The b values for each situation are obtained by correlation methods and express the extent to which the given response involves the given trait.

Motivation. Besides the T 's, which are abilities, there are others which, as stated, represent drives and sentiments (acquired attachments). The former are the primary motivators, stabilized in expression by the sentiments and governed and directed by self-sentiment and the superego, with characteristics defined by the discovered factor loadings.

Objective devices for measuring motivation prove to separate into I (integrated) and U (unintegrated) components, and a good many inferences about conflict, suppression, and repression can be drawn from their relationship in a particular case. Factoring of motivation data by Cattell and his co-workers has confirmed the existence of repression, projection, and other Freudian mechanisms, as well as the existence of complexes. Eysenck, however, has rejected psychoanalytic terminology in regard to any resemblances found.

Developmental sequences. Twenty years of work by correlational methods have been devoted largely to determining temperamental and dynamic structures and demonstrating that they hold true across different ages and cultures. Recently, through Eysenck's application of extroversion-introversion to concepts of inhibition in learning and through Cattell's reduction of personality change observations to algebraic matrix analyses in "adjustment process analysis," this theory of personality structure has become increasingly related to learning theory. Both authors stress the reality of constitutional and genetic components and the methods which enable their identification. They have also accorded the generalization of learning, experience, and specific "social molds" a significant role in determining the observed structures.

Environmental determinants. Cattell has suggested three classes of learning experiences: classical conditioning, reward learning, and integration learning. Eysenck has focused on the application of conditioning principles to personality change in "behavior therapy." One of the main learning issues in multivariate experimental theory at the moment concerns the manner in which specific learning experiences generate the general factor dimensions found structurally. Ferguson, Tucker, and Fleishman have investigated this in relation to ability. Similarly, Cattell's "adjustment process analysis" represents an attempt to account for the impact of sociological institutions and acquired social roles.

NEUROLOGY

NEUROLOGY

Chapter 10

NEUROLOGY

The inclusion of a section on neurology in a psychiatric text is unusual but appropriate, for organic diseases of the central nervous system may cause both psychiatric and neurological symptoms. Understanding the function and dysfunction of the mind must be based upon knowledge of the structure and diseases of the brain. This chapter is an outline of those features of neurology essential to the psychiatrist's understanding of the complex structure from whence psychiatric illnesses arise. With rare exceptions the spinal cord and peripheral nerves and muscles have been excluded from this presentation.

The chapter is divided into four sections: 10.1, the neurological evaluation, including electroencephalography and other laboratory techniques useful in establishing a diagnosis; 10.2, the anatomy and physiology of the central nervous system with a review of the mental and emotional syndromes associated with lesions of different parts of the brain; 10.3, clinical neurology correlated with neuropathology; and 10.4, other neurological syndromes including those diseases which do not present well defined pathology, with special attention to epilepsy, symptoms of pain and dizziness, and mental and emotional syndromes commonly encountered in neurology. This material is not intended as a substitute for a neurological text, for the data presented must be necessarily brief. Only basic facts are recorded in the section on anatomy and physiology. Similarly, only the highlights of neurological diseases can be included in the subsequent sections. The diseases have been outlined so as to enable the physician to approach the neurological differential diagnosis in a systematic, logical manner.

10.1 THE NEUROLOGICAL EVALUATION

SEYMOUR SOLOMON, M.D.

Neurological Evaluation of the Adult

In making a neurological diagnosis, one must first decide whether the illness is psychogenic, patho-

physiological, or organic. If the last, the anatomic location and then etiology must be established. Finally, the precise name of the disease may be appended.

The history. An adequate history is probably the most important step in establishing a diagnosis. The source and reliability of the history should be recorded. The patient's age, sex, and handedness are best noted at the outset. A detailed and chronological resume of the present illness is the essential feature of the history. Each complaint should be evaluated with regard to onset, duration, and frequency of occurrence. Note should be made of aggravating as well as alleviating factors. Specific qualities of the complaint must be evaluated. For example, if pain is a chief complaint, the type of pain and its location and radiation are important. If dizziness is the chief complaint, the exact meaning of the term to the patient must be elicited, for "dizziness" may mean a spinning sensation, an unsteady sensation, a feeling of generalized weakness or faintness.

To be sure that the patient has not omitted pertinent information, it is wise to review a set of neurological symptoms. Thus, the patient should be specifically questioned with regard to the occurrence of headache, dizziness, episodes of fainting or faintness, "fits" or convulsions, shaking or trembling, unsteadiness or incoordination. He should be asked about past or present weakness, stiffness or paralysis, aches or pains, numbness or tingling, either focal or generalized. The patient should be queried as to symptoms referable to the special senses. Was there a history of double vision, spots before the eyes, temporary blindness, or blurring of vision? Did the patient experience ringing in an ear or hearing impairment in one or both ears? Was the sense of taste or smell impaired? Perversions of these special senses might be neglected by the patient unless specifically questioned. "Do you ever smell or taste anything peculiar? Do you ever hear or see things out of the ordinary?" Visceral symptoms may be important neurological phenomena. Has there been a history of disturbance of swallowing or speech, an alteration of bladder or bowel control? In female patients the history of pregnancy and menstruation may be significant. Sexual potency or recent change in sexual activity are important features of the history. Alteration in sleep pattern may be pertinent. Symptoms of mental illness should be sought. Indications of organic disease manifested by memory impairment or confusion are as important as symptoms of psychological disturbance manifested by personality change, anxiety, or past history of delinquency or "nervous breakdown."

The past medical history should include queries as to trauma, surgery, and medical illness (e.g., diabetes and hypertension) as well as history of allergy, exposure to toxins, and weight gain or loss. The use of medication or drugs, particularly in the recent past, should be noted. Sometimes, defects in the patient's memory for past illnesses may be overcome by inquiring about all past hospitalizations.

Social history should include occupation and drinking and smoking habits. Family history should note not only the diseases which caused death, but the presence of epilepsy or mi-

graine headaches. Other diseases, both mental and neurological, particularly with regard to motor activity, may have been present and yet may not have been related to death.

Physical examination. A general physical examination need not be considered a routine part of the neurological examination, but evidence of acute or chronic illness should be noted, as well as indications of recent weight loss or excessive weight gain. Obvious physical deformities should be recorded. The blood pressure and pulse of both arms may be significant. Portions of the physical examination may be singled out as particularly appropriate. If there is suspicion of cerebral metastases in a woman, palpation of the breasts for primary carcinoma would be indicated. One should listen for a heart murmur on suspicion of subacute bacterial endocarditis. Other infectious processes affecting the central nervous system would lead one to examine the lungs for evidence of infection. Hepatic or splenic enlargement should be sought if there is suspicion of leukemia. Hair texture and distribution over the body may be disturbed in hypopituitarism, and evidence of testicular atrophy may be important in certain neurological diseases, e.g., myotonic dystrophy. Poor or absent peripheral pulses in the extremities may be a clue to similarly diseased vessels in the head.

Neurological examination

Mental status. An evaluation of the mental status has been covered in detail in another chapter of the book and only an outline of the tests for intellectual functioning and emotional status is included at this time. It is essential to note the patient's level of consciousness. His language can then be carefully evaluated.

Intellectual functions. If the patient is alert, the degree of his attention or distractibility and cooperativeness is pertinent. It is essential to know the degree of the patient's orientation to place, time, and person. His memory, with regard to both remote and recent events, must be tested. The patient's retention and immediate recall are examined by asking him to recite a span of three to five digits in sequence both forward and backward. General knowledge is tested by asking him the names of well known individuals. (It is surprising how many "normal" people do not remember the first name of the President.) Calculation can be judged by asking the patient to subtract 7's from 100 in serial fashion. Reasoning can be evaluated by noting the patient's ability to deal with abstract concepts. (For example, he might be asked the similarity between an apple and an orange and asked to interpret a simple proverb.)

Emotional status. The patient's emotional status should be noted, particularly with regard to his perception of reality, the presence of illusions or hallucinations. The production of his thought processes, their progression, preoccupation, and content are important observations. The patient's judgment and insight should be noted. His affect and its appropriateness, depression or euphoria, emotional lability and degree of anxiety are pertinent. Behavior, neatness, mannerisms, and other forms of motor activity can be seen. Determination of the patient's motivation and special appetites may require more thorough evaluation. Psychometric studies have been discussed elsewhere in the text.

Language disturbances. Disturbance in language is in itself a manifestation of organic mental disease. The term "dysphasia" is usually more appropriate than the term "aphasia," for rarely is communication completely lost. Defects in language can best be evaluated by dividing those which are primarily disturbances in reception from those which are primarily an impairment of expression. Each of the latter may again be divided into spoken and written language. It must be emphasized, however, that defects of a single type are unusual. First to be noted is spontaneous speech. When expression is impaired, very little spontaneous speech is evident, whereas if the defect is primarily receptive, incoherent jargon or "word salad" speech often occurs. In testing for receptive dysphasia, one must find out if the patient can understand the examiner. Ask him to repeat words or phrases. Can the patient carry out simple commands? (His inability to understand verbal instructions should be clearly

differentiated from the physical inability to carry them out.) Can the patient pick out an object or point to an object that is named? Can he recognize familiar sounds such as running water? Similar questions can be asked in writing. The inability to understand the meaning of written symbols is termed "dyslexia" or "alexia" and is often associated with receptive dysphasia or aphasia.

The patient should then be tested for the ability to express himself. Motor or expressive dysphasia will be manifested in its mildest forms by the inability of the patient to express the proper word within a sentence and, in its most severe forms (aphasia), by the inability of the patient to express himself vocally in any way. Can the patient name objects and name parts of the body? Can he then express himself in more complex terms? Can the patient write spontaneously or write from verbal dictation or copy words and sentences? A defect of expression in written language is termed "dysgraphia" or "agraphia" and may be associated with motor dysphasia or aphasia.

Inability to recognize objects or symbols by specific senses is called "agnosia." Visual agnosia is the inability to recognize a familiar object visually. Auditory agnosia is the loss of ability to identify familiar sounds. Tactile agnosia (better known as astereognosis) is the inability to recognize familiar objects placed in the hand, in spite of the preservation of superficial and deep sensations in the extremity. Defective cortical motor integration results in apraxia, i.e., the incapacity to carry out purposeful or skilled acts while maintaining the motor and coordinative abilities to perform these acts. Such simple acts as drinking from a cup or closing a safety pin may be tested. More complex defects of cortical integration are impairment of right and left discrimination and the inability to recognize body parts.

Most language dysfunctions occur with lesions of the dominant hemisphere. In approximately 90 per cent of right-handed individuals and 50 to 90 per cent of left-handed individuals the left cerebral hemisphere is dominant. The lesions causing aphasic phenomena are not so precisely localized as was once thought. Extent of cerebral disease is at least as important a factor as the location of the lesion. Lesions in or near Broca's area, i.e., the inferior posterior portion of the frontal lobe of the dominant hemisphere, are most often associated with expressive dysphasia. Receptive dysphasia is commonly present with lesions of the temporal lobe. Dyslexia occurs with lesions of the temporal and occipital areas. Dysgraphia is associated with lesions in the posterior frontal, parietal, or temporal lobes.

Examination of the head and neck. Inspection may reveal asymmetries of the head and unusual postures of the neck. On palpation of the scalp one may note exostosis as that overlying a meningioma. The temporal, carotid, and radial pulses should be palpated and cervical lymph nodes noted. Direct percussion of the skull, comparing the right with the left side, will sometimes reveal dullness overlying a subdural hematoma. Auscultation over each eyeball (allowing the opposite eye lid to open will greatly diminish adventitious muscle sounds) may reveal bruits of a vascular malformation or of collateral circulation associated with carotid artery stenosis. Bruits over the carotid arteries or subclavian arteries may also be indicative of stenosis of these vessels. (Note that the loudness of a bruit does not have a direct relationship to the degree of stenosis.) Mobility of the neck to passive movement may be diminished after cervical injuries. Restriction of neck flexion as an indication of meningeal irritation may be associated with the following signs. The Brudzinski sign is characterized by pain in the neck and back with flexion of the thighs on an attempt to flex the neck passively. The Kernig sign is manifested by pain of the back and neck with tendency to flex the neck slightly upon straight leg raising.

Examination of the cranial nerves

I. Olfactory nerve. The patient is asked to identify familiar odors such as coffee or tobacco. Each nostril is individually tested. The most common causes of defects in olfactory sensa-

tion are not due to disease of the first cranial nerve, but rather to obstruction of the nasal passage or disease of the nasal mucous membrane (e.g., allergic rhinitis). Thus, bilateral impairment of the sense of smell is usually not significant. Loss of the sense of smell on one side, in the absence of local causes, may be due to an olfactory groove meningioma.

II. The optic nerve. The patient's visual acuity is determined either by using a Snellen chart or, at the bedside, by having the patient read ordinary newsprint. Each eye should be tested individually, both with and without the patient's corrective lenses. Ophthalmoscopy is then performed, and the optic discs and retinal arteries and veins are noted. Retinal hemorrhages and exudates may be seen in a large variety of diseases, particularly of a vascular nature. Pallor and sharpness of an optic disc may be due to optic atrophy. Hyperemia of the disc, blurring of its margins, disappearance of the physiological cup, venous engorgement, and absence of venous pulsations are indications of papilledema.

The most common causes of increased intracranial pressure and papilledema are intracranial masses or hemorrhages; block of cerebrospinal fluid outflow or absorption; and swelling of the brain due to traumatic, inflammatory, toxic, or metabolic factors (for example, water intoxication or pseudotumor cerebri; see Section 10.4). Papilledema may also be due to optic neuritis (see Section 10.3) and other lesions within the orbit. Extracranial factors sometimes cause papilledema. This sign may be due to increased venous pressure, as seen in cardiovascular diseases (for example, pulmonary emphysema), or to increased arterial pressure or flow (for example, malignant hypertension or arteriovenous fistula). Papilledema occasionally occurs with acute polyneuritis or spinal cord tumors. The mechanism of papilledema in these diseases is uncertain; but markedly increased spinal fluid protein, usually present, probably impairs absorption of the fluid. Other extracranial diseases that may be associated with papilledema are anemia, polycythemia, and other blood dyscrasias; vitamin A poisoning in children; hypoparathyroidism; and adrenal hypofunction (Addison's disease).

The visual field of each eye can be tested by having the patient cover one eye, look at the examiner's nose, and note the examiner's moving fingers at the periphery of the field. Each quadrant, as well as each half of the right and left visual fields, are tested. When more precise information is required, standard perimetry and the tangent screen examination are necessary to determine the exact peripheral and central visual fields. The most common examples of visual field defects are the following. An irregular central scotoma within one visual field is usually a residual of retrobulbar or optic neuritis, as seen in multiple sclerosis. Enlargement of the blind spot occurs in papilledema. Constriction or loss of the visual field in one eye is due to a lesion of the optic nerve. Bitemporal hemianopsia is caused by a lesion of the optic chiasm. Homonymous hemianopsia is associated with a lesion of the opposite optic tract. Homonymous superior temporal quadrantanopsia is found with a lesion of the opposite temporal lobe. Homonymous hemianopsia with macular sparing is due to a lesion of the opposite occipital lobe.

III, IV, and VI. The oculomotor, trochlear, and abducens nerves. These nerves are tested together since they supply the muscles of eye movement and, in the case of the oculomotor nerve, the constrictors of the pupil and the elevator of the eyelid. The size, shape, and symmetry of the pupils are noted. The response of the pupil to accommodation is tested by noting the pupillary constriction as the patient focuses from a distant to a close object. The reaction of the pupil to light is seen by shining a light into each eye from the side. (Direct approach of the light might cause the pupils to constrict because of accommodation.) Both direct and consensual pupillary reactions should be tested. A unilaterally dilated pupil may be the first sign of oculomotor nerve compression. Constriction of a pupil associated with ptosis and impairment of sweating over the ipsilateral forehead are manifestations of Horner's syndrome indicative of an ipsilateral sympathetic nerve pathway lesion.

The range of extraocular movements is noted by asking the patient to follow the movement of the examiner's finger in all directions of gaze. The examiner should pause briefly in every direction to look for nystagmus. Ptosis of the lid is a sign of involvement of the oculomotor nerve, but the palpebral fissures may be asymmetrical from other causes. (For example, disease of the facial nerve causing weakness of the orbicularis oculi muscle will result in a larger palpebral fissure on the side of facial involvement.) A complete loss of function of the oculomotor nerve will be manifested by the patient's inability to deviate the eye up, down, or medially, with associated ptosis of the lid and dilation of the pupil. In lesions of the trochlear nerve affecting the superior oblique muscle, the patient will have difficulty looking in the down and out direction. As a consequence, the head will be tilted toward the shoulder of the opposite side. With disease of the abducens nerve, the patient will not be able to look laterally. In all cases the patient will complain of double vision. Involvement of the third, fourth, or sixth cranial nerves, may be due to direct or indirect compression of the nerve fibers within the cranial cavity or to lesions of the cranial nerve nuclei in the brain stem. In patients with conjugate gaze palsy, the eyes will be deviated away from the side of an irritative cerebral lesion or toward a destructive cerebral lesion.

V. The trigeminal nerve. Sensation of the face and cornea is first tested by observing the patient's blink response when a wisp of cotton lightly touches the cornea. The same wisp of cotton can then be used to test touch over the three divisions of the trigeminal nerve (forehead, cheek, and chin), comparing the right to the left side. Response to light pin prick is tested in a similar distribution. (When hypalgesia is mild, temperature impairment over the same distribution confirms the objective nature of the defect.) Loss of corneal reflex may be the first sign of trigeminal nerve compression by an ipsilateral acoustic neuroma, and analgesia over one side of the face may be seen in brain stem infarction (e.g., the lateral medullary syndrome). The masses of the temporal and masseter muscles are palpated with the jaws tightly closed. An open jaw will deviate toward a weakened external pterygoid muscle. A jaw jerk is elicited by tapping the middle of the chin with a reflex hammer while the patient's jaw is loosely open. Hyperactivity of this reflex may be a manifestation of pyramidal tract disease. The trigeminal nerve carries pain and touch sensations from the mucous membranes of the nose and mouth, but these need not be routinely tested.

VII. The facial nerve. The muscles innervated by this nerve are observed at rest and after asking the patient to show his teeth and wrinkle his forehead. Sometimes minimal asymmetries noted on movement of the face to command are exaggerated during expression of emotion or other spontaneous activity; other times the reverse is true. The strength of the orbicularis oculi is tested by attempting to open the patient's eyes against his resistance. Paralysis or weakness of all the facial muscles on one side, including the forehead, is indicative of ipsilateral lower motor neuron disease as seen in Bell's palsy. If the muscles of the forehead are spared, the facial weakness is presumed to be due to a contralateral corticobulbar lesion, e.g., cerebral infarct. The sensory portion of the facial nerve carries taste from the anterior two thirds of the tongue. The patient is asked to protrude the tongue and indicate presence of taste by raising his hand. Sugar and later salt in solution are placed on the anterior portion of the tongue. The rapidity of responses on one side is compared with that on the other.

VIII. The acoustic nerve. This nerve is composed of two portions, the cochlear and vestibular nerves. During a routine neurological examination only the cochlear nerve is examined. Auditory acuity may be determined by noting how far from his ear the patient is first able to hear a watch tick (the examiner may use himself as a control). The Weber test is performed by placing a vibrating tuning fork on the midline of the patient's skull. If the sound is referred to one ear, the test is considered positive. When air conduction deafness is present

(as due to accumulation of wax in the canal or in otitis media), the Weber test lateralizes to the affected ear; if there is nerve deafness, the Weber refers to the normal ear. The Rinne test is performed by placing the vibrating tuning fork on the mastoid portion of the skull behind the patient's ear. When the patient can no longer hear the sound, the fork is then placed next to the ear. Under normal circumstances, air conduction of sound is better than bone conduction. Bone as well as air conduction is impaired on the side of nerve deafness. Audiometry is of value in quantitating hearing loss precisely. When nerve deafness is suspected, the caloric test should be performed to evaluate the vestibular portion of the acoustic nerve. Injection of 2 to 15 ml. of ice water into the external auditory canal normally evokes, within a few seconds, vertigo, nystagmus (with fast component to the opposite side), and past pointing to the stimulated side. When the acoustic nerve is compromised, loss of auditory acuity and of caloric response is evident on the side of involvement. Other tests of the vestibular system are less practical and not commonly used.

IX and X. The glossopharyngeal nerve and vagus nerve. These are tested together. The gag reflex is tested by touching each side of the pharynx with a tongue depressor. Bilateral impairment of the gag reflex need not be abnormal, but loss of gag reflex on one side and pulling up of the soft palate toward the opposite side is indicative of involvement of the ninth and tenth nerves. Hoarseness may be an indication of weakness or paralysis of a vocal cord. Difficulty in swallowing (dysphagia), noted earliest with liquids, is indicative of bulbar (medullary) or pseudobulbar disease. Dysarthria may be due to motor disease affecting the tongue or other portions of the vocal mechanism, but more commonly it is due to defects in coordination of the speech mechanism secondary to cerebellar pathway disease. The glossopharyngeal nerve carries taste from the posterior third of the tongue, but this is not routinely tested. The autonomic functions of the vagus nerve, having to do with cardiopulmonary activity, are usually noted during the general physical examination.

XI. The spinal accessory nerve. The trapezius muscle is tested by having the patient shrug his shoulder against resistance. The sternocleidomastoid muscle is examined by having the patient turn his head against resistance. These muscles are affected by lesions compressing the nerve at the jugular foramen or, less commonly, by lesions in the lower medulla. The trapezius and, less commonly, the sternocleidomastoid may also be weakened or paralyzed owing to a contralateral cerebral lesion. (Note that the sternocleidomastoid muscle is commonly uncrossed in its supranuclear innervation.)

XII. The hypoglossal nerve. The protruded tongue normally is in the midline. It will deviate to the weakened side, that is, ipsilateral to the lesion, if the lower motor neuron is involved and contralateral to the lesion in upper motor neuron disease. If lower motor neuron disease is present, atrophy or fine fasciculations of the tongue may be seen on the side of involvement.

Cranial nerve signs. The following is a summary of cranial nerve signs that may be found in a lesion of one cerebral hemisphere, e.g., cerebral infarct or tumor. (Roman numerals refer to cranial nerves.)

- I. Contralateral homonymous hemianopsia
- III, IV, VI. Conjugate deviation of eyes away from side of the irritative lesion or toward side of the destructive lesion
- V. Contralateral impairment of pain and touch over the face and diminished corneal reflex
- VII. Contralateral paresis of the face, but not including the forehead
- XI. Contralateral weakness of the trapezius muscle and ipsilateral weakness of the sternocleidomastoid muscle
- XII. Contralateral weakness of the tongue

Pseudobulbar palsy. This is a syndrome characterized by symptoms implicating the brain stem but due to bilateral disease of supranuclear corticobulbar fibers, most commonly mul-

multiple small cerebrovascular lesions. (Since most bulbar musculature has a bilateral cortical representation, a unilateral supranuclear lesion will not cause bulbar signs.) Dysarthria and dysphagia are most common. Speech has a nasal, slurring, and often explosive quality, and the volume of voice is diminished. Chewing and swallowing are impaired, and food may accumulate in the mouth with drooling of saliva and frequent choking. The patient's gait is often impaired, particularly because of dysequilibrium. All movements may be slow and poorly performed. The facies may be flattened as in parkinsonism. Exaggerated emotional responses are prominent and spontaneous laughing and crying frequently occur. The latter are involuntary and unassociated with appropriate emotions. Gag reflexes are preserved, and deep reflexes, including the jaw jerk, are hyperactive.

Motor examination. Posture and contractures and deformities of the extremities or trunk should be noted. The muscles are inspected and palpated, and symmetry, atrophy, fasciculations, and tenderness are noted. Accurate measurement of circumferences of the extremities documents the degree of atrophy. Fasciculations may be evident in lower motor neuron disease but are not pathognomonic. Muscle tenderness is frequently present in a patient with myositis. Consistency of muscle may be fibrous or rubbery in myopathies or myositides. A prolonged depression occurs when a myotonic muscle (thenar eminence or tongue) is briskly tapped. The hand grip of a myotonic will be slow to relax. Muscle tone, i.e., the resistance to passive movement, is characterized by flaccidity in lower motor neuron disease; knife clasp spasticity or simple increase in tone with an upper motor neuron lesion; and rigidity (often of the cogwheel type) in certain extrapyramidal diseases, e.g., parkinsonism. Voluntary muscle strength must be determined. If there is suspicion of nerve root or peripheral nerve involvement, individual muscles of the extremities are specifically examined. With minimal spinal cord involvement, slight differences may exist between the strength of the upper and lower extremities. In the presence of minimal unilateral cerebral disease, slight weakness of the contralateral extremities may be manifested first in the extensor and supinator muscles of the upper extremity and in the flexor and internal rotator muscles of the lower extremity. Thus, with the patient's eyes closed and the arms extended, one may see slight downward drift, flexion and pronation of the affected upper extremity. With the patient prone, slight downward drift of the affected flexed lower leg may occur (Barre's sign), and, with the patient supine, slight external rotation of the leg and slight foot drop may be noted.

Classification of involuntary movements

a. **Extrapyramidal dyskinesias:** The involuntary movements associated with disease of the basal ganglia tend to occur at rest in contrast to the intention tremor of cerebellar disease. They are invariably increased by emotional stress and disappear during sleep.

Parkinsonism is characterized by a resting rhythmic tremor affecting the extremities, particularly distal parts, and, in the hands, having a "pill-rolling" quality. Cogwheel rigidity and bradykinesia are other features of the parkinsonian syndrome. Akathisia, the inability to sit or stand still, may be seen in this condition. The predominant lesion in parkinsonism is located in the substantia nigra and globus pallidus, to a much lesser extent in the putamen.

Athetosis is manifested by slow writhing, twisting movements affecting predominantly the distal portions of the extremities; associated similar movements of the face cause grimacing. Spasticity is present more often than hypotonicity. The globus pallidus is more severely involved than other basal ganglia.

Chorea is characterized by rapid, irregular, asymmetrical jerks of the extremities, particularly the distal portions. The movements are purposeless but terminally may be turned into semipurposeful movements. Hypotonicity is usually present. The disease in childhood is a manifestation of rheumatic fever

(Sydenham's chorea). In adult life, Huntington's chorea or senile chorea are the underlying diseases. The caudate and putamen are the basal ganglia predominantly involved.

Dystonia musculorum deformans or torsion spasm is manifested by slow writhing torsions of the trunk and pelvic and shoulder girdles. Scoliosis and lordosis are common. The pathology of this condition is not well defined, but the globus pallidus appears to be more involved than other nuclei of the basal ganglia.

Hemiballismus is characterized by unilateral violent flail-like movements of the extremities. The individual appears to be trying to throw his extremity away from his trunk. A lesion (usually vascular) of the subthalamic nucleus causes this condition.

b. Diseases of the liver and brain: Wilson's disease is manifested by one or a combination of irregular resting or intention tremors or chorea-athetoid movements. The basal ganglia, cerebellum, and cerebral cortex are implicated in this disease.

Asterixis is a flapping motion of the hands, best demonstrated with the hands and arms extended. It is characteristic of impending hepatic coma.

c. Tics or habit spasms: These are sudden, repetitive, irregular twitches and are almost always psychogenic. They usually consist of grimacing, blinking, or other facial movement, twisting of the head and neck or shrugging the shoulders. Torticollis, the involuntary persistent turning of the head to one side, may be the first sign of dystonia musculorum deformans but is more often of psychological origin.

d. Restless legs syndrome: The individual experiences peculiar, uncomfortable (sometimes painful) crawling sensations in the muscles or "bones" of the lower legs. These sensations are partially relieved by almost constant movement of the legs. The phenomena occur at rest, especially at night. No cause is known.

e. Convulsive seizures: Epilepsia partialis continua is manifested by slow continuous clonic movements of a portion of one extremity (for example, the thumb) lasting for hours or days. Paramyoclonus multiplex consists of jerking or brief single contractions of muscle groups scattered over different areas of the body. Status epilepticus is included for purposes of completeness but is rarely a difficult diagnostic problem, except for those rare cases of petit mal status, wherein slow clonic movements of the trunk and upper extremities may occur. All of the above are associated with epileptogenic lesions of the cerebrum.

Coordination. Coordination may be divided into equilibratory and nonequilibratory functions.

Equilibratory functions. These are noted by observing the patient's customary gait as well as by watching him walk on heels and toes. A tendency to drift to one side, as in ipsilateral cerebellar disease, may be exaggerated by having the patient walk with eyes closed or in tandem fashion (touching the heel of one foot to the toe of the other). The associated movements of arm swing may be lost in ipsilateral cerebellar or contralateral extrapyramidal or pyramidal tract disease. The patient should be asked to stand erect with feet together, first with eyes open and then with eyes closed. The Romberg sign is an inability to maintain posture under the latter circumstance and is usually indicative of posterior column disease of the spinal cord, but the sign may also be present with a cerebellar lesion. Impairment of truncal equilibrium may be noted by the awkward manner in which the patient arises from a supine position or gets up from or sits in a chair. These manifestations of truncal ataxia suggest midline cerebellar disease.

Nonequilibratory functions. Coordination of the extremities is tested by having the patient touch the heel of one foot to the knee of the other leg and then run the heel down the shin of the leg, first with eyes open and then with eyes closed. The patient is asked to touch his nose and then the examiner's finger, first with the eyes open and again with eyes closed. The ability to alternate movements rapidly is tested by having him tap his foot on the floor and pat his thigh with his palm and then with the dorsum of his hand. A defect in rapid alternating

movements is called dysdiadochokinesis. Rebound phenomenon occurs with inability to check a movement quickly. This may be tested by suddenly, and without warning, releasing an extremity that has been forcefully restrained. Fine skills are noted by observing the patient button his clothes and write. Defects in any of the above coordinative skills suggest ipsilateral cerebellar disease. Ataxia may also be caused by position sense impairment or weakness, and one must always note whether the degree of ataxia is commensurate with or out of proportion to the weakness.

Signs of cerebellar or cerebellar pathway disease. Defective equilibrium and posture are associated with tendencies to deviate toward the side of the lesion. Associated movements are impaired on the affected side. Ipsilateral incoordination is manifested by ataxia of the extremities with intention tremor, dysmetria, past pointing, dysdiadochokinesis, and rebound phenomenon. There is ipsilateral decrease in muscle tone, and pendular reflexes may result. Fatigability and slowness of movement are common. A scanning (staccato) type of speech and nystagmus may be present.

Classification of gait disturbances

a. **Neurogenic alterations of gait:** Upper motor neuron disease is characterized by a spastic gait. In a hemiplegic, the lower extremity is extended and circumducted while walking. In paraparesis, such as that seen with spinal cord disease, the gait is stiff-legged and wide-based. In paraparesis of cerebral palsy (diplegia) adductor spasm causes a scissors gait, wherein extended lower extremities are alternately crossed.

Lower motor neuron disease causes a steppage gait. The leg of the flaccid foot is raised higher than usual and the foot is slapped down to prevent stumbling over the toe.

Diseases of the basal ganglia. In parkinsonism, gait is characterized by small steps and festination, i.e., a tendency to accelerate. Chorea-athetotic gait is intermittently irregular and jerking. Dystonic gait is characterized by pelvic and truncal torsion. In Wilson's disease, both cerebellar ataxia and extrapyramidal features may be present.

Cerebellar disease is characterized by a staggering gait with tendency to fall toward the side of the lesion.

Proprioceptive defect, particularly when due to disease of the posterior columns of the spinal cord, is manifested by an ataxic wide-based gait that is worse at night or with the eyes closed.

b. **Gait disturbances not associated with neurological disease:** A limping gait may be due to pain or orthopedic defect of the leg, low back, or hip. A mincing gait is often seen in patients with spinal rheumatoid arthritis, in senile individuals, and in male homosexuals. A waddling gait is associated with bilateral dislocations of the hip or muscular dystrophy.

The gait of hysteria may be bizarre and variable. The disability is often so great that, if organic, one would expect the patient to fall frequently, but the contrary is the case. Astasia-abasia is the inability to stand or walk in spite of adequate muscle strength and coordination.

The sensory examination. This portion of the examination is often the most difficult and frustrating. Both patient and examiner must be alert and cooperative. Since it is not practical to stimulate every square centimeter of the body, in eliciting sensory signs the examiner must have an idea of the location of the neurological lesion for which he is searching. Only gross lesions will be found by asking the patient to differentiate pain from touch sensations. In almost all instances one must ask the patient to differentiate a stimulus applied to a normal portion of the body from the same stimulus applied to a portion of the body that is presumably affected. Thus, in searching for a peripheral nerve defect, the examiner asks the patient to compare a stimulus in the area of presumed deficit, with a similar stimulus over the opposite extremity. When searching for polyneuropathy manifested by distal sensory impairment, one asks the patient to compare the sensation over the toes or fingers with a similar sensation over the more proximal portions of the extremity. In the search for a spinal level, the examiner

asks the patient to compare a stimulus below the presumptive sensory level with one above. Finally, when dealing with an intracranial lesion, one asks the patient to compare a sensation over the affected side of the body with a similar sensation over the presumably unaffected side. During all sensory testing it is preferable to have the patient's eyes closed. Superficial touch sensation is examined by means of a wisp of cotton, superficial pain by a pin or, preferably, a pin-wheel. Sensitivity to temperature may be tested by using test tubes containing hot and cold water. (If the latter are not readily available, the "cold" handle of the reflex hammer may be used.) Vibration sense is evaluated by means of a tuning fork (preferably with frequency of 236 cycles per second), placed on bony prominences of the extremities. Position sense is examined by passively and slowly moving the patient's finger or toe, asking him to indicate promptly the direction of movement. The examiner should take care that pressure on the skin of the finger or toe cannot be used by the patient in interpreting the direction of movement; this is best done by grasping the sides of the digit. Deep pain can be tested by squeezing the Achilles tendon, the muscles of the calf or forearm. Impairment of vibration, position, and deep pain sensations are manifestations of disease of the posterior columns of the spinal cord, whereas impairment of superficial pain, touch, and temperature sensations are indicative of lesions of the spinothalamic tracts. Any modality may be impaired by a lesion of its pathway from the peripheral nerve through the spinal cord and brain stem to the thalamus and parietal lobe.

Fine discriminatory sensations require the cerebral cortex for interpretation. In cerebral defects, especially of the parietal lobe, extinction of the stimulus on the opposite side of the body may occur when right and left sides of the body are simultaneously stimulated by touch or pin prick, with the patient's eyes closed. Two-point discrimination is tested by simultaneously applying two stimuli in close proximity and asking the patient whether he feels one or two points. The distance between points that can be distinguished differs from one part of the body to another; as might be expected, this discrimination is best in the fingers. As with all of the above studies, the normal part must be compared with the presumptive abnormal part. Stereognosis is tested by asking the patient, with his eyes closed, to identify familiar objects placed in his hand. One tests for graphesthesia by asking the patient to recognize letters or numbers written on his skin. The patient is asked to differentiate the textures of cotton, silk, and wool. It is obvious that defects of these "cortical sensory phenomena" will not implicate the cortex or cerebrum if more peripheral sensory pathways are affected.

Reflexes. Again, one must compare symmetrical areas and apply the stimulus with equal intensity to relaxed extremities. Tendon and periosteal reflexes are elicited by tapping the tendon or the bony prominence associated with a specific muscle. Contraction of the muscle may be graded as slight, normal, or hyperactive. In the upper extremities, the reflexes most commonly tested are the biceps (C5-6), the triceps (C6,7,8), the radial (C5-6), and ulnar (C6-7). In the lower extremities, the patellar (L2,3,4) and the Achilles (S1-2) tendons are tapped. Ankle clonus may be elicited by briskly dorsiflexing the foot and maintaining sustained pressure. Clonus is a manifestation of hyperreflexia but, as with all forms of hyperreflexia, need not be pathognomonic of pyramidal tract disease. Loss or decrease of tendon reflexes is found in lower motor neuron disease or myopathy. The superficial reflexes are tested by stroking the skin with a semisharp object. The four quadrants of the abdomen should be tested (D7,8,9 upper; D11-12 lower). The cremasteric reflex (D12-L1) is elicited by stroking the medial aspect of the thigh. Stroking the medial aspect of the buttock normally causes the skin to tense; this is the gluteal reflex (L4-5, S1-2).

Certain pathological reflexes are indicative of pyramidal tract disease. The Babinski sign is elicited by stroking the lateral aspect of the sole of the foot with a semisharp object.

Flexion of the toes is the normal response; dorsiflexion of the big toe and sometimes spread of the other toes is the abnormal response. The Chaddock sign (stroking the lateral aspect of the dorsum of the foot), the Oppenheim sign (forcefully stroking the anterior surface of the shin), and the Gordon sign (squeezing the calf muscle), show toe responses like that of the Babinski sign but are not as pathognomonic of pyramidal tract involvement as is the latter. Hoffmann's sign is elicited by forcefully flicking downward the distal portion of the patient's middle finger. In a positive response, flexion and adduction of the thumb occurs. An alternate method of obtaining the same response by abruptly tapping the volar surface of the distal portion of the middle finger is Tromner's sign. Both the Hoffmann and the Tromner signs have the same significance as deep reflex hyperactivity. They are indicative of pyramidal tract disease when unilateral but may be due to tension if bilateral.

The autonomic nervous system. Observation of the patient often provides valuable information about his autonomic nervous system. Signs of endocrinopathies (see Section 10.4) may be evident on inspection. Evaluation of vital signs should be part of the general physical examination. Trophic changes of the skin and mucous membrane and of the hair and nails and alteration of vasomotor tone of the extremities may give many clues of autonomic dysfunction. Note should be made of alterations in secretions, i.e., perspiration, salivation, and lacrimation. Obesity and other alterations of fat metabolism may be readily evident. Certain disease of bones and joints may be of trophic nature (e.g., the Charcot joint of tabes dorsalis). Horner's syndrome has been mentioned above. Sphincter tone must be evaluated, especially in the incontinent patient.

There are many special tests of autonomic function. Most common is the test for localized disturbance in perspiration performed by sprinkling a starch and iodine powder over the skin. Moisture will reveal the iodine pigment.

Neurological Evaluation of the Child

History. A child's history is obtained in a manner similar to that outlined for the adult but with different emphasis. Review of systems will prove to be less helpful in the child. The social history will concentrate on environmental factors. The family history must be more thorough.

The importance of the prenatal, perinatal, and postnatal history cannot be overemphasized. Was the mother's pregnancy normal or was there a history of vaginal bleeding? Did the mother experience illness during the pregnancy and what drugs, if any, were taken by her? Was the labor unusually prolonged or in any other way abnormal? Was the delivery of the infant difficult or in any other way potentially traumatic? Was the infant of good color and did he cry immediately? The neonatal history should include the weight of the infant at full term, or the extent of the prematurity.

The assessment of the neurological status of the infant and child is primarily a measurement of the maturation of the nervous system. The developmental history is essential. Figures 1 and 2 indicate milestones in the maturation of a child. The parents may not be aware of all of the features in the infant's development but often can remember some of the following events. The infant should begin to lift his head while prone from the time of his birth and lift it well by 4 months of age. He should begin to smile at 2 months of age and laugh, as well as recognize his mother, by 4 months of age. The baby should sit unsupported by 8 months of age and begin to crawl and creep between 10 and 12 months of age. He should wave "bye-bye" at 10 to 11 months of age. At 11 months of age he should pull himself up to the standing position and begin to walk with support at 1 year. The word "mama" becomes meaningful at 10 months of age and by 1 year an additional one- to

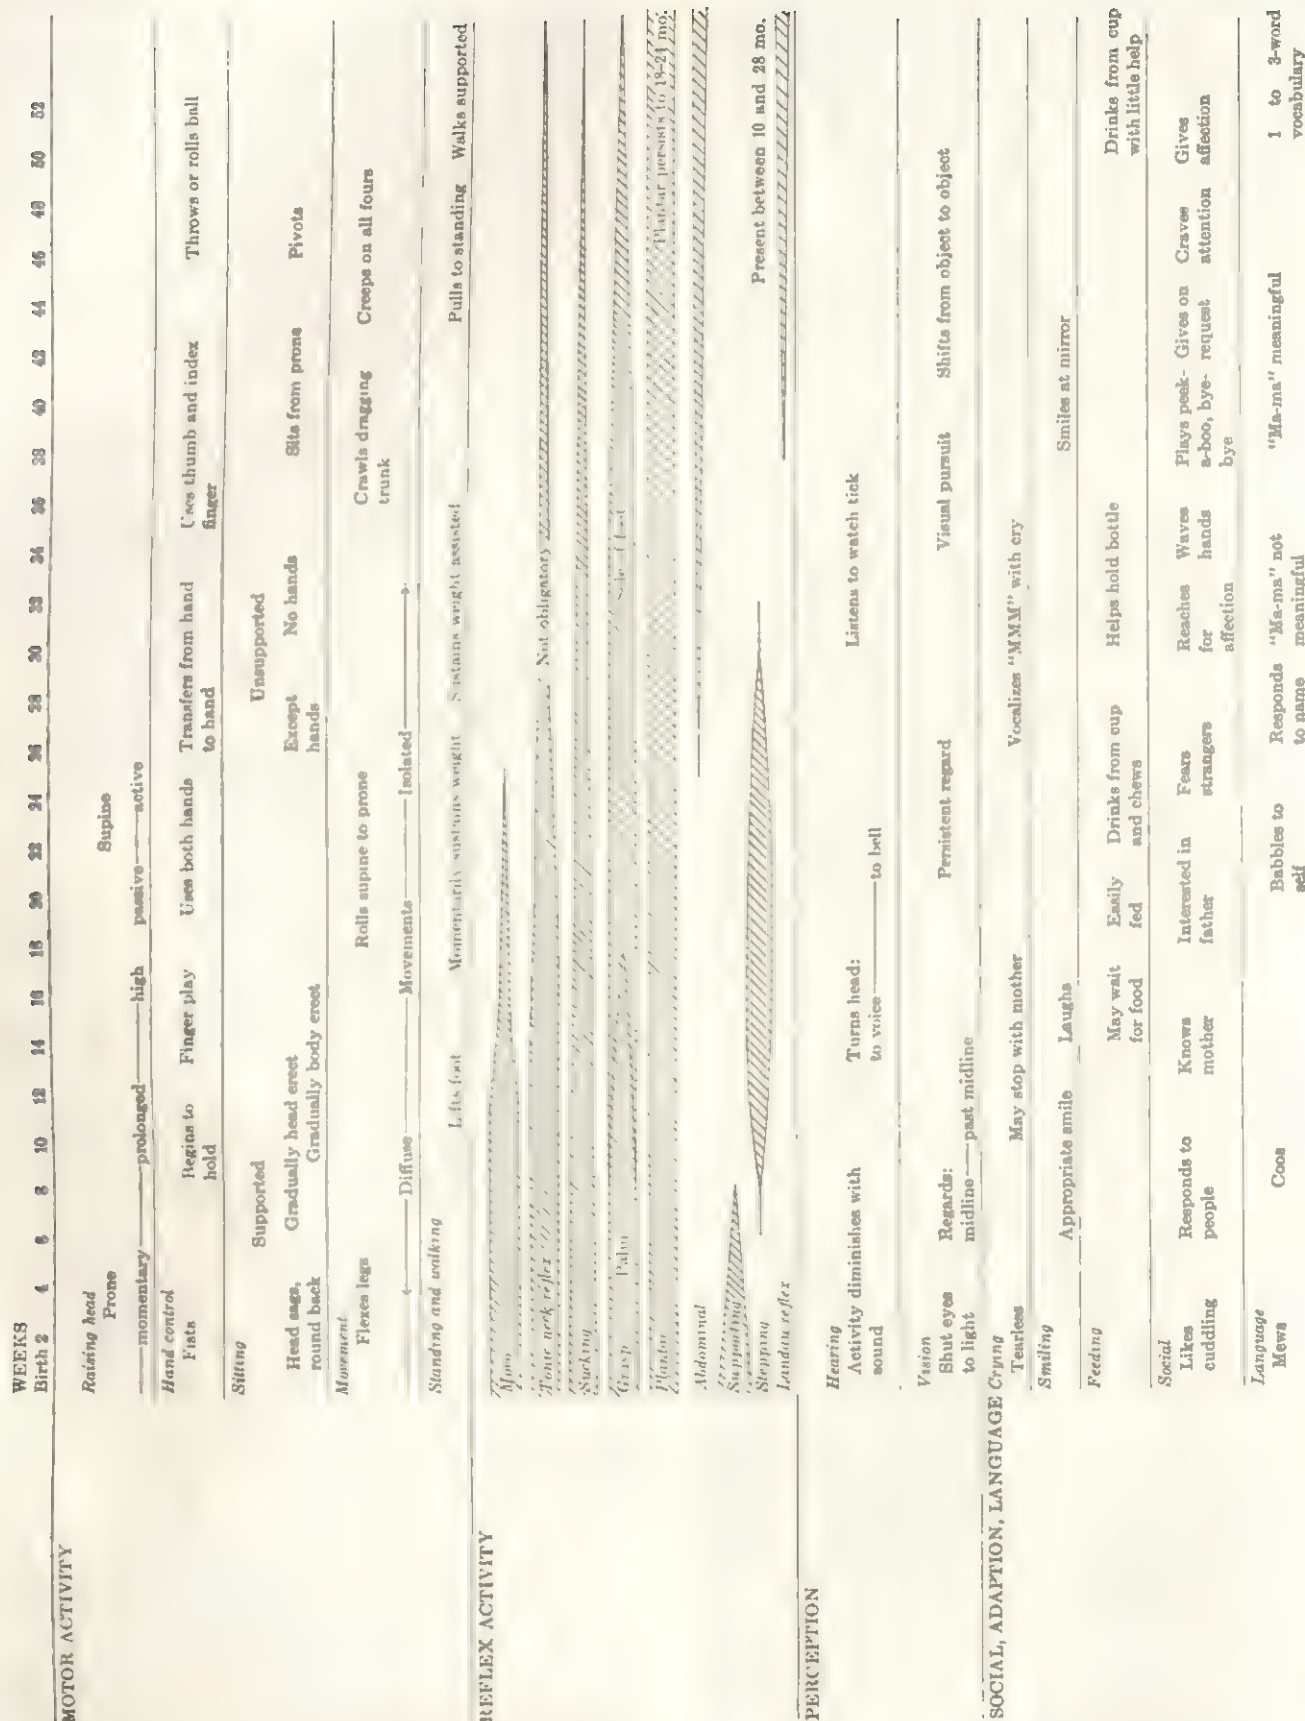

FIGURE 1. Developmental landmarks during the 1st year of life.

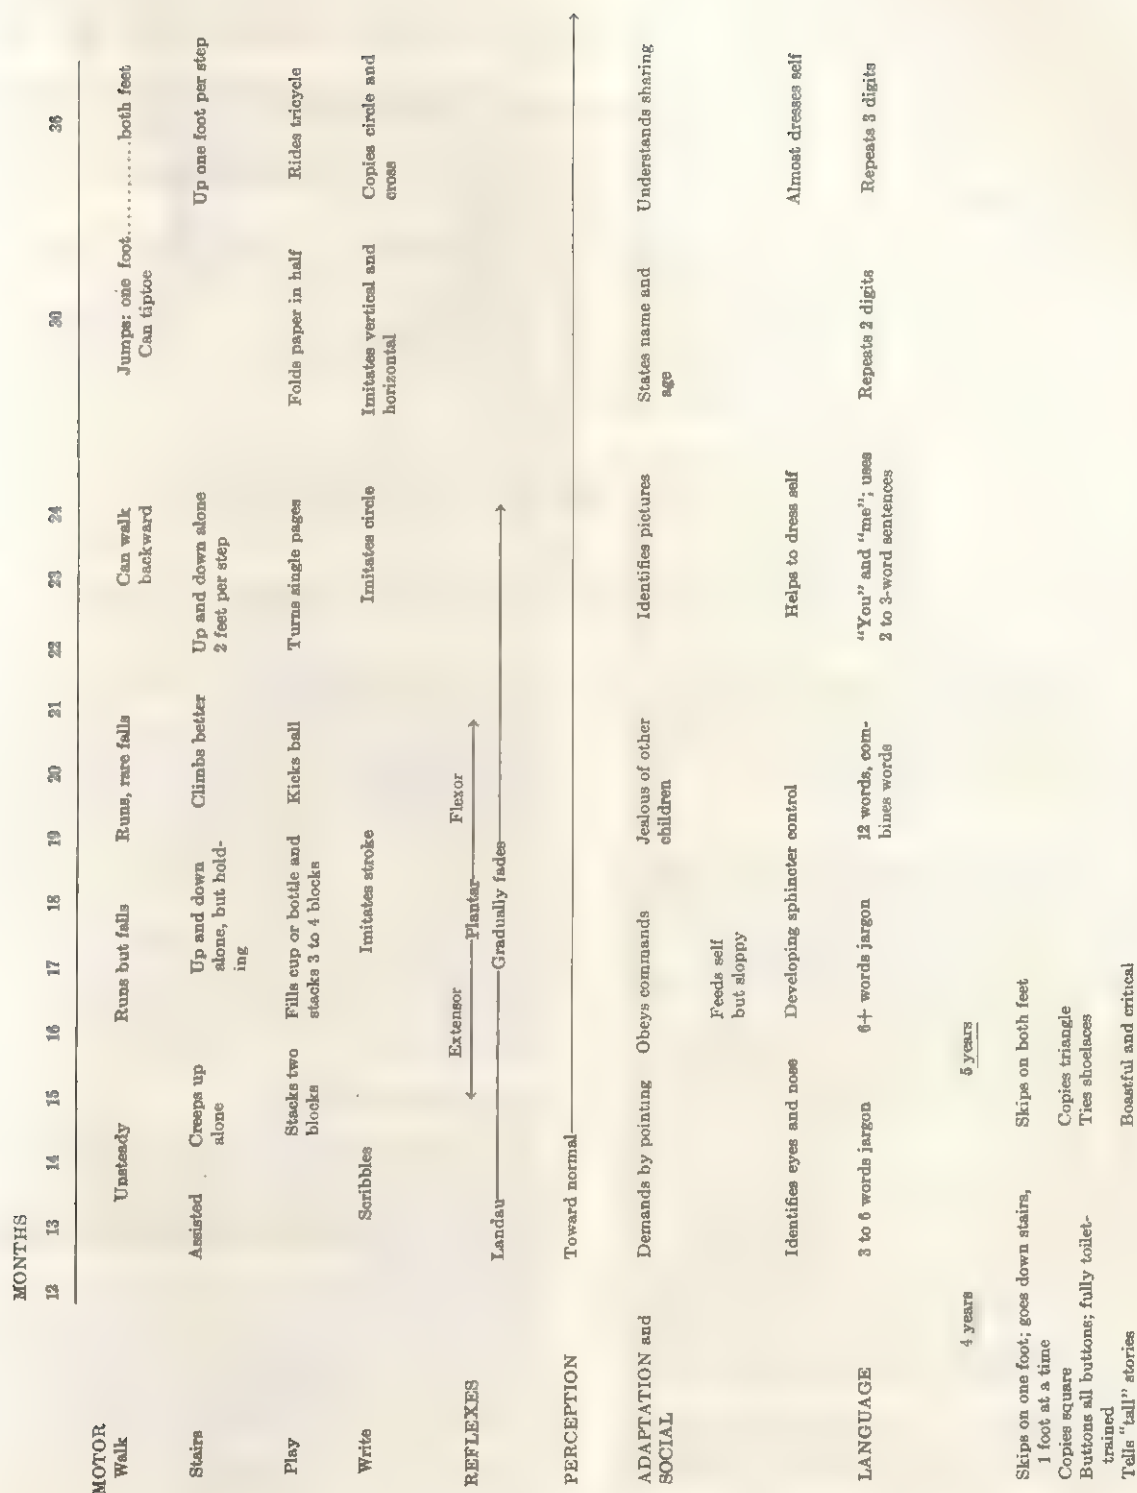

FIGURE 2. Developmental features during the ages 1 to 5 years.

three-word vocabulary should be evident. There is a wide range of normal, of course, and slow development of one or two features should not be taken as evidence of significant retardation. For example, although the average child walks without assistance soon after 1 year of age, retardation of gait is not considered present before 18 months of age. In addition to these landmarks, other history during the 1st year of life may be pertinent. Was the child "colicky"? Did the infant sleep excessively; i.e., was she an unusually "good" baby? On the other hand, was evidence of hyperactivity manifested during the 1st year of life?

Neurological examination. An essential objective of the neurological examination of the infant is an assessment of the maturity of the patient as related to his chronological peers. Repeated observations are often essential before drawing conclusions. (Tremulousness, for example, may disappear after the hungry child is fed.) The patient is often too young for the examiner to conclude that a lesion is static or progressive without reexamination weeks or months later. As with the adult, the general physical examination may be helpful. For example, the child may exhibit the skin manifestations of a phakomatosis or the skeletal characteristics of mongolism.

The neurological examination of the infant must differ from that of the adult in that one must first evaluate those features which will least disturb the child and then progress to those parts of the examination which may require restraint. (For example, the ophthalmological examination is performed early in the neurological evaluation of an adult, but last when examining an infant.) In performing the neurological examination, one observes the social adaptability and language of the child, his motor activity, perception, and, finally, postural reactions and reflex activity. These features have been outlined in Figures 1 and 2. Other tests, as discussed for the adult, are integrated into this general pattern of examination wherever applicable. Certain reflexes (or, more properly, reactions) found in infants will be described here. Other features of the examination peculiar to infants will also be noted.

Special reflexes

Moro reflex. This reflex is elicited by sudden mild extension of the neck or any stimulus which suddenly startles the infant. In response to such stimuli, there is extension of the trunk and upper extremities, then flexion of the upper extremities, with or without extension of the lower extremities. This reflex is normally present at the time of birth, diminishes by 3 to 4 months, and should be absent after 6 months of age.

Tonic neck reflex. Turning of the head to one side when the infant is supine results in extension of the arm and leg of that side, with flexion of the opposite extremities. This reflex, normally present at the time of birth, diminishes after 4 to 6 months, but fragments of this reaction may be present during the remainder of the 1st year.

Sucking reflex. Touching a finger to the infant's lips elicits the sucking reflex. This reflex diminishes after a few months and is absent after 1 year.

Grasp reflex. The infant's hand and fingers flex when the examiner's finger is placed in the palm of the hand, and similarly the foot and toes flex when the examiner's finger is pressed to the ball of the foot. The palmar grasp reflex diminishes after a few months and disappears after 4 months, but the grasp reaction of the plantar surface of the foot may persist into the 2nd year.

Plantar reflex. Stimulation of the lateral aspect of the sole of the foot elicits an extension of the big toe (Babinski sign). This sign is normally present from the time of birth until 1½ years or, at the most, 2 years of age.

Abdominal reflex. Contraction of the abdominal wall results from stroking the overlying skin. The abdominal reflex may not be easily elicited until 6 to 12 months of age.

Supporting reflex. With the infant held upright but at a somewhat acute angle to the examining table, extension of the

legs occurs when the infant's feet touch the table. This reflex, present at birth, ends after 1 to 2 months of age.

Stepping reflex. With the infant held in a position similar to that described for the supporting reflex, stepping movements should be noted between 2 and 6 months of age and proper walking movements should be evident after 10 to 11 months of age.

Landau reflex. With the infant held prone, he assumes the position of hyperextension of the spine and neck. Flexion of the head in that position results in flexion of the spine and extremities. The reverse phenomena are observed with the patient held supine. The Landau reflex occurs normally between 10 and 28 months of age.

Additional factors for consideration. The posterior fontanel should be closed by 6 weeks of age. The anterior fontanel should close between 9 and 18 months of age.

Measurement of the head size is important, particularly serial measurements for evidence of increasing hydrocephalus.

Percussion of the skull may elicit a "cracked pot" sound as evidence of suture separation due to increased intracranial pressure.

Transillumination of the skull may aid the diagnosis of hydrocephalus, porencephalic cyst, or subdural hematoma.

Bruits over the eyeballs are commonly heard in infants and young children and should not be considered abnormal.

Eye movement may be tested by rotating the infant's head and noting whether the eyes appear in all directions of gaze (doll's eye maneuver).

Movements are diffuse rather than isolated and voluntary movements are not evident until 4 to 6 months of age.

By 9 months of age, alterations in motor tone, posture, or use of extremities can be considered abnormal (see the discussion of minimal brain dysfunction in Section 10.4). (1) Alteration of muscle tone is manifested by asymmetry of tone or generalized hypertonicity. (2) Abnormal posture of extremities is revealed by persistence of abduction, adduction, flexion, or extension of the arms; persistence of extension or scissoring of the legs; or persistence of fisted hands or other abnormal hand postures. Abnormal posture of the trunk, or head and neck is noted by a rounded back when sitting; or head sagging forward, tilting or retracting. Abnormal posture when standing is manifested by the infant attempting to stand on an unusually narrow base, failing in attempt to support the body while standing with assistance, or standing on toes. (3) Altered use of an arm or hand is revealed by the tendency to avoid use of one extremity, difficulty in retaining a grasped object, persistence of grasp, other impairment of grasp, or maldirection in reaching for an object.

Electroencephalography

This topic is discussed in greater detail than other diagnostic measures, not necessarily because it is a more useful test in the neurological evaluation of the patient, but because it is a test more commonly used by psychiatrists.

The electroencephalogram (EEG) is a record of the electrical activity of the brain. This activity represents synaptic potentials of apical dendrites in the cerebral cortex. Only the sum of inhibitory and excitatory potentials of large groups of neurons is recorded. Great amplification is required for purposes of recording; a 7-mm. deflection of the recording pen is usually calibrated to correspond to 50 μ V. In interpreting a tracing, the electroencephalographer scans the entire page as a single picture, rather than evaluating each individual wave. The interpretation is therefore, in large part, subjective.

FIGURE 3. A, The normal adult EEG. At the arrow the eyes of the patient were open; note the "blocking" of α rhythm. B, The normal low voltage fast adult EEG.¹

Analysis of the EEG. In analyzing the EEG, three major components must be considered. (1) The individual waves are evaluated with regard to their frequency, form, and amplitude. (2) Series of waves, i.e., their rhythmic qualities, are analyzed. (3) The locations of waves are studied, particularly with regard to differences between one cerebral hemisphere and the other.

Probably the most important feature of the EEG is the frequency of the electrical activity. The frequencies of an adult record normally range from 8 to 13 cycles per second, α (alpha rhythm). Other frequencies are often abnormal. Frequencies of 4 to 7 per second are termed theta activity; 1 to 3 per second, delta activity. Activity faster than α rhythm, 14 to 30 per second, of voltage averaging 20 μ V. or more, is called beta activity.

The wave forms are normally those of a simple sinusoidal pattern, although complex forms with faster rhythms superimposed upon slow frequencies may also be noted. Fast waves have sharp features. Cycles less than $\frac{1}{2}$ sec. in duration are considered spikes and are most often abnormal.

The amplitude of a normal adult EEG is usually "moderate," i.e., it averages 50 to 75 μ V. Considerable variation in voltage may normally occur. The cerebral electrical activity of a normal awake adult consists of moderate voltage sinusoidal waves occurring at 8 to 13 (predominantly 9 to 10) cycles per second. These waves occur in rhythmic series that form spindle patterns and are located primarily over the occipital areas of the head (Figure 3A). Low voltage fast activity also may be normal (Figure 3B).

The normal cerebral electrical activity will be altered with changes in the conscious state of the patient and in response to stimuli and will vary from childhood to adult life.

Effect of state of consciousness on EEG. The conscious state of the individual has a tremendous influence on the EEG. Decrease in frequency and increase in amplitude occur as the individual becomes drowsy and falls asleep. In an adult, during early drowsiness, α rhythm decreases in amplitude and sometimes in frequency. In the transition between drowsiness and sleep, a relatively flat record alternates with series of α rhythm and low voltage θ activity, especially over the temporal parietal areas, is noted (Figure 4A).

During light sleep, vertex sharp waves (formerly termed biparietal humps) occur singly or in short series. Groups of positive (downward deflection) spikelike waves over the bioccipital areas may occur in the adult record. Theta activity is predominant over the convexity of the head. Sleep spindles (sigma rhythm) averaging 14 per second, especially over the parietal areas, are noted (Figure 4B). In moderately deep sleep, the activity further decreases in frequency to the δ range and increases in voltage. Sleep spindles decrease from 14 to 12 per second and become predominantly frontal. During deep sleep, very slow irregular δ activity is noted, especially over the convexity of the head, with superimposed θ activity and spindles of 10 per second present in a more generalized fashion. Stimulation during sleep will evoke an arousal response manifested by a K complex (one or two high voltage slow waves resembling vertex sharp waves or humps). In light sleep, fast activity may briefly follow the latter and there is quick return to the waking state, whereas in deep sleep, a lightening of the sleep pattern may occur. Variations from these adult sleep patterns will be described in the discussion of the child's EEG. Rapid eye movements (REMs) during sleep are associated with dreaming, although not invariably so. During this phase of sleep there is desynchronization of the sleep pattern. The electrical activity is similar to that of the transitional stage between drowsiness and sleep, with low

¹ The designation of electrode positions is that adopted by the International Federation of Societies for Electroencephalography and Clinical Neurology: F_p (frontal pole), F (frontal); C (central), P (parietal); O (occipital), T (temporal); C_v (vertex), A (ear). Even numbers as subscripts indicate the right hemisphere, odd numbers the left.

FIGURE 4. A, The normal adult drowsy EEG. Note the dropping out of α rhythm and its replacement by low voltage slow activity. B, The normal sleeping EEG with 14 per second sleep spindles and bilaterally synchronous sharp waves of predominantly central origin.

voltage activity of variable frequency. In addition, saw-tooth waves are usually noted. Periods of REM sleep occur throughout normal sleep but are not necessarily indicative of lightening of the depth of sleep (see Section 2.4).

Response to stimuli. The response of the cerebral electrical activity to stimuli is routinely tested. The α rhythm will normally disappear during stimuli. The EEG is performed with the patient's eyes closed, and opening of the eyes will interrupt the series of α rhythm. Mental stimulation (asking the patient to perform a complex mathematical task) will "block" the α rhythm. Emotional tension often obliterates α rhythm, and the normal EEG of an unusually tense person may consist of nothing more than low voltage fast activity.

Lambda waves are sharp or saw-tooth waves over the occipital areas evoked by the patient's visually scanning an object such as a picture. MU rhythm is a series of waves within the 7 to 11 per second range that appear as the written letters M or U over the central areas of the head and are abolished by movement or stimulation, particularly of the hands.

Hyperventilation is performed for 3 min. A buildup of slow activity, i.e., decrease in frequency and increase in voltage, commonly seen in children (Figure 5, left side), may persist for as long as 100 sec. after the cessation of hyperventilation. A relatively low blood sugar and the erect posture increase the response to hyperventilation. The exact mechanism of slow activity during hyperventilation is still uncertain, but it is agreed that cerebral hypoxia is the basic underlying factor.

Photic stimulation is attained by means of a bright flashing stroboscope held close to the patient's closed eyes. A "driving response" often can be evoked over the bioccipital areas. This normal response consists of bilaterally symmetrical activity, synchronous with the flash frequencies, usually near or within the α range (Figure 6A). Sometimes the EEG frequency is a subharmonic or multiple of the flash stimuli. Photic stimulation may evoke a photomyoclonic response characterized by twitches of the face and eyes with associated muscle artifact in the EEG. This should not be interpreted as a manifestation of epilepsy.

EEG characteristics of children

EEG of the premature and newborn. The EEG of the premature child will manifest low voltage slow activity of 1 to 3 per second over the occipitotemporal areas, with superimposed low voltage fast activity. These features alternate with long periods of electrical silence. No difference can be discerned between the waking and sleeping state.

The newborn, while awake, will exhibit a pattern similar to that of the premature, but even flatter. The most common state in the newborn is that of drowsiness. The EEG of this transitional state consists of low voltage, almost flat, activity except for occasional random slow waves. Activities of 4 to 6 per second may be noted over the central areas and are sometimes saw-toothed. These transitional state patterns closely resemble those of rapid eye movement sleep, and the percentage of time spent in these states decreases as the infant grows older. When the newborn is asleep, the record reveals high voltage (150 μ v.), 1 to 3 per second activity alternating with a relatively flat record (*tracé alternant*).

EEG during the 1st year of life. During the 1st year of life, the waking record shows the gradual development of occipital rhythm beginning with random low voltage slow activity. By 3 to 4 months of age, frequencies of 4 to 6 per second are noted and can be interrupted when the eyes are opened. Toward the end of the 1st year, the activity further increases in frequency and voltage.

A great many changes occur in the maturation of sleep activity during the 1st year of life. By the 6th to the 8th week of age, well defined sleep spindles (series of 14 per second activity) are seen over the frontocentral areas of the head. After 3 to 6 months of age, long series of high voltage slow activity occur during drowsiness. By 3 to 6 months of age, sharp waves over the central areas of the head (biparietal humps) are noted during light sleep. After 6 to 8 months of age, paroxysmal series of high voltage slow activity are seen, particularly over the central areas of the head, during drowsiness. There is little arousal response in the newborn, but after the 2nd month, and especially by 6 to 8 months of age, K com-

FIGURE 5. Hyperventilation. On the *left*, the normal buildup of high voltage slow activity in a 9-year-old child. On the *right* the superimposed spike activity alternating with the high voltage slow waves is an abnormal response.

FIGURE 6. Photic stimulation. *A*, The normal response to photic stimulation. plexes occur and are followed by series of moderate to high voltage slow activity.

EEG after the 1st year of life. The waking EEG after the 1st year of life reveals a gradual increase in frequency (especially over the occipital areas). Between 2 and 9 years of age, frequencies increase to approximately 7 to 9 per second, but a great deal of slower activity is also present (Figure 7).

Waves as slow as 2 per second may be seen as late as 8 years of age, but this activity either is of low voltage or occurs as single waves. Between 10 and 16 years of age, frequencies within the adult range of 8 to 13 per second are seen. Less and less slower frequencies are noted within the faster rhythms. Particularly between the ages of 8 and 15 years, MU rhythms appear.

FIGURE 7. A, The normal child's EEG, age 3 years. B, The normal child's EEG, age 9 years. Note the increase in frequency but with persistence of scattered and underlying slow activity.

Drowsy EEG activity in children after the 1st year of age is characterized first by disorganization of the record. Increase in voltage and in diffuse slow activity with 1 to 3 per second frequencies over the posterior portions of the head are noted. The steady slow activity of drowsiness usually disappears after 6 years of age. Paroxysmal bilaterally synchronous high voltage slow activity during drowsiness rarely persists after 15 years of age.

Central sharp waves of very light sleep occur in a bilaterally synchronous fashion. The first stage of sleep is manifested by 14 per second sleep spindles. With moderately deep sleep, there is an increase in 4 to 6, then 2 to 3 per second activity, and 12 per second sleep spindles are noted. Finally, in deep sleep, very high voltage, very slow activity is seen with no further evidence of spindles or central sharp waves. Continuous slow activity, following the K complex of arousal, usually disappears by the 15th year or earlier. Approximately between the 10th and the 15th year, paroxysmal slow activity may follow the K complex.

Abnormal characteristics of the EEG. It must be emphasized that these features are abnormal only when not accounted for on the basis of youth, change in the conscious state of the patient, or response to stimulation.

Frequency. Activity slower than 8 per second, i.e., θ or δ activity, particularly if occurring in series, is abnormal. Generalized slow activity is suggestive of diffuse organic disease or a pathophysiological metabolic cerebral disturbance. Focal slow activity (Figure 8) is indicative of underlying organic disease although minimal θ activity over the bimtemporal areas is of doubtful significance. Activity faster than α rhythm (β activity), is abnormal; however, the clinical significance of β activity is less well defined than that of slower activity. Generalized fast activity is seen in some drug intoxications. Particularly if intermittent, β activity may be noted in records of patients with convulsive disorders. Focal fast activity is usually indicative of underlying organic disease that may be epileptogenic.

Voltage. Low voltage diffuse activity may be a manifestation of suppression of cerebral electrical activity seen in severe

organic disease. Low voltage activity of a focal nature indicates underlying disease, for example, a subdural hematoma. Very high voltage activity may precede a seizure.

Sharp waves and particularly spikes. Anterior temporal spike activity is most commonly associated with psychomotor seizures (Figure 9). Other spike activity, or spike and wave activity, may be indicative of an underlying epileptogenic lesion. Multiple spike foci in children suggest seizure activity or mental or physical retardation. Spikes in children's EEGs may change location from one time to another. Fourteen and 6 per second positive spikes (Figure 10A) may be associated with visceral phenomena or behavioral symptoms and are discussed elsewhere (see below).

Paroxysmal activities. Bilaterally synchronous paroxysmal slow activity is seen in patients with generalized convulsive disorders and in disease or dysfunction of deep midline structures. Three per second spike and slow wave bilaterally synchronous paroxysmal bursts are characteristic of petit mal epilepsy (Figure 11). Spike and wave bursts of other frequencies are often indicative of grand mal (Figure 12). Mitten patterns are spike and wave complexes over the frontoparietal areas, sometimes seen as the last portion of a sleep spindle in adults. Gibbs has classified these mittens by the frequency of the "thumb" or spike. Mittens of $\frac{1}{6}$ to $\frac{1}{4}$ sec. in duration are associated with deep organic disease; mittens of $\frac{1}{6}$ to $\frac{1}{4}$ sec. ("A" type) are correlated with parkinsonism; mittens of $\frac{1}{4}$ to $\frac{1}{2}$ sec. ("B" type) are most often seen with psychoses and seizures.

Determination of EEG abnormality depends upon a large number of variables. Only two examples are cited. There may be many single slow waves in a normal record, but the same slow waves occurring in a few groups (series) are usually abnormal. Slightly slow activities over the temporal areas may be normal, but the same activity over the occipital areas is often abnormal.

Abnormal EEG patterns of the 1st year of life. Abnormal slow, fast, or spike wave activities may occur in infants. In addition, the record of an infant that is too well organized or appears more mature than expected for the age is probably abnormal. Occipital spike activity in infants and children is often associated with seizures, prematurity and visual symptoms. The following EEG abnormalities, peculiar to the infant,

FIGURE 8. *A*, Focal 2 per second δ activity from the F7 and T3 electrodes, indicative of a left anterior temporal lobe lesion, in this case a glioblastoma multiforme. *B*, Slightly slow activity of 7 per second, predominantly from the T6 electrode, indicative of a right posterior temporal lobe lesion, in this case an infarct.

FIGURE 9. Psychomotor (temporal lobe) epilepsy characterized by random spikes from the T1 (left anterior temporal) electrode. Note phase reversals from this area.

carry a very poor prognosis for physical or mental development.

Hypsarrhythmia. This pattern is characterized by high voltage irregular spike and slow wave activity occurring frequently and asynchronously, with marked disorganization of the record (Figure 13). Such activity, seen in patients with infantile spasms (see Section 10.4), commonly resolves after 2 years of age and is rare after 4 years. Physical or mental retardation is almost invariable.

Extreme spindles. These are sleep spindles of higher voltage, occurring in a wider distribution and more continuously than normal sleep spindles. They usually are seen after 6 to 7 months and before 5 years of age. This pattern is indicative of mental retardation, often with cerebral palsy, particularly of the extrapyramidal type.

Diagnostic value of the EEG. There are no EEG patterns pathognomonic of specific disease (with the

FIGURE 10. *A*, 14 per second positive spikes seen in a 10 year old with behavior disorder and intermittent episodes of abdominal pain; *B*, paroxysmal irregular spike and slow wave bursts occurring in a bilaterally synchronous fashion at approximately 4 per second, seen in another 10-year-old child with sudden paroxysms of abdominal pain (abdominal epilepsy).

FIGURE 11. Petit mal epilepsy characterized by bilaterally synchronous, 3 per second spike and slow wave activity.

possible exception of petit mal). The response of cerebral electrical activity to injury of any type is relatively limited, and it makes little difference whether the injury is organic (anatomic) or pathophysiological. The initial response of the EEG to injury is manifested by slow activity. As a rule of thumb, the slowest frequencies correspond to the most

severe lesions. Spike or sharp activity is usually a manifestation of the resolution of injury. Focal spike activity may indicate that an old or relatively old lesion has become epileptogenic. Focal slow activity is indicative of an underlying anatomic lesion but the lesion does not always exactly underlie the site of maximum EEG abnormality. A lesion within a

FIGURE 12. Grand mal epilepsy manifested by paroxysmal bursts of high voltage polyspike and irregular slow wave activity occurring in a bilaterally synchronous fashion.

FIGURE 13. Hypsarrhythmia characterized by asynchronous bursts of high voltage polyspike and irregular slow wave activity occurring in a haphazard fashion from all leads (age, 8 months).

cerebral hemisphere will often be associated with slow activity that is reflected predominantly over the occipital lobe in children, or over the temporal lobe in adults. It is not practical to consider the EEG characteristics of every neurological disease, and only the large etiological categories are discussed.

Neoplastic cerebral disease. This is usually manifested by focal δ activity (Figure 8A). If the tumor is deep or causes increased intracranial pressure, diffuse slow activity may occur.

Cerebellar tumors in adults sometimes are associated with bifrontal or frontotemporal slow activity whereas such tumors in children are often associated with bioccipital slow activity. The EEG is often normal in slowly growing extracerebral intracranial tumors such as meningiomas. Sometimes focal δ activity may be found in a relatively "silent" area of the brain, giving the clinician the only, or major, clue to the presence of an underlying neoplasm. On the other hand, the EEG focus is not sufficiently reliable to allow surgery without more definitive study.

Vascular lesions. These are usually associated with focal

FIGURE 14. A, diffuse moderate to high voltage very slow (δ) activity seen in a patient with severe encephalitis; B, diffuse θ activity seen in a patient soon after cerebral trauma; C, diffuse fast (β) activity seen in a patient with barbiturate intoxication.

θ activity (Figure 8B). If the cerebral infarct is recent, large, or superficial, or if a hematoma is present, focal δ activity may occur. Scattered small vessel disease often results in diffuse or scattered θ activity. A subarachnoid hemorrhage is most commonly associated with diffuse slow activity, but in some instances focal EEG changes may be the only clue to the site of the ruptured aneurysm. Serial studies are extremely valuable in differentiating neoplastic from vascular disease.

Inflammatory diseases. Inflammatory diseases affecting the cerebrum as a whole, such as meningitis or encephalitis, usually manifest diffuse slow activity (Figure 14A) with occasional focal qualities. An abscess, on the other hand, causes focal δ activity just as any other space-occupying lesion. In children, the EEG is useful in differentiating encephalitis associated with convulsive seizure from a benign febrile seizure, for the EEG usually is normal in the latter. Serial studies may be helpful in evaluating meningitis of children, for, if improvement in the EEG does not occur after two weeks, one should suspect the development of sinus thrombosis, subdural empyema, or subdural effusion. Subacute inclusion body encephalitis is often characterized by an unusual EEG pattern of sharp and slow wave complexes occurring periodically every 2 to 8 sec.

Cerebral trauma. Cerebral trauma may produce focal or diffuse EEG abnormality (Figure 14B) and sometimes paroxysmal slow activity. (The latter may be due to the shearing effect of the brain on its pedestal, the brain stem, with associated dysfunction of the diencephalon.) In children, the response of the EEG to trauma is more severe than in the adult, but the return to normal is faster. A comatose patient manifesting a normal EEG probably has severe brain stem injury with its concomitant poor prognosis. Diffuse slow activity soon after severe cerebral trauma may obscure focal slow activity overlying an area of contusion. Focal depression of amplitude in a patient with head trauma raises the suspicion of an underlying subdural hematoma. Since a spike focus is usually the result of an old injury, such a focus seen on the day of cerebral trauma or a few days after, indicates that the focus is not related to the recent trauma. The incidence of

post-traumatic epilepsy in those patients who develop a persistent spike focus after closed head injury is estimated to be 10 to 15 per cent.

Metabolic or degenerative diseases. These illnesses usually cause diffuse slow activity in the EEG, sometimes with slight focal prominence. Hepatic encephalopathy is manifested by bilaterally synchronous slow waves predominant over the anterior areas, often accompanied by random sharp activity forming "triphase waves." Jakob Creutzfeldt disease, during one stage in its course, may reveal generalized periodic high voltage sharp or spike activity. The EEG is a relatively poor guide to the activity or severity of metabolic cerebral disease, for clinical changes often precede changes in the EEG.

Drugs and toxic substances. These have a nonspecific effect upon the EEG, causing either diffuse slow activity or diffuse fast activity or, sometimes, both. The patient in deep coma with diffuse fast activity in the EEG raises the strong suspicion of barbiturate narcosis (Figure 14C). Other drugs which may cause fast activity in the EEG are methyl phenylethylhydantoin (Mesantoin), diphenylhydantoin (Dilantin), meprobamate, glutethimide (Doriden), chlordiazepoxide (Librium), diazepam (Valium), and, in high dosage, amphetamine. Primidone (Mysoline) may be associated with either fast or slow activity. The phenothiazine derivatives often cause fast activity at low dosage, but slow activity in higher dosage. Most other drugs or noxious agents are associated with diffuse slow activity. Dilantin and Mesantoin slow the α rhythm, as do morphine and meperidine (Demerol). In stuporous patients who have been taking anticonvulsant medication, the EEG helps to differentiate subclinical status epilepticus, manifested by almost continuous paroxysmal activity, from drug intoxication with resultant diffuse fast or slow activity.

Other extracerebral factors may change the EEG, particularly in children. Alterations in electrolytes and fluid balance (water intoxication), endocrine disturbances, burns, and trauma to the body are all associated with diffuse slow activity in the EEG. In children, mild fever, stress of surgery, or systemic illness, especially leukemia, often cause diffuse slow activity.

Epilepsy. The EEG is of greatest value in epilepsy (see

Section 10.4). The classical characteristics are paroxysmal abnormality or focal spike abnormality. The EEG is most often abnormal in petit mal; up to 90 per cent of such cases reveal an abnormal EEG. The EEG may be normal in from 30 to 50 per cent of other forms of epilepsy. The percentage of records that reveal abnormality in epileptic patients will depend to a great extent upon the EEG laboratory, for abnormalities will be found in a greater percentage of patients who have had tracings of long duration (or repeated number), and during drowsiness and light sleep. After the history, the EEG is the most important factor in the diagnosis of epilepsy. Petit mal (Figure 11) is characterized by bilaterally synchronous, symmetrical 3 per second spike and wave bursts. Grand mal (Figure 12) is manifested by paroxysmal slow or spike activities or, most commonly, a combination of the two. This activity will be bilaterally synchronous if the seizures are generalized or will have a focal component if the seizures arise in one of the cerebral hemispheres. Focal convulsive disorders will reveal focal spikes or sharp waves and often associated slow activity. The most common example is a spike focus over the anterior temporal lobe in temporal lobe or psychomotor epilepsy (Figure 9).

The EEGs certainly may be normal in the presence of organic brain disease. This is particularly true if the lesion is deep, small, or old. For example, the EEG is often normal early in the course of multiple sclerosis because the lesions are small, scattered, and subcortical. The EEG may be normal in epilepsy because the duration of the record was not long enough to "catch" intermittent paroxysmal activity. Finally, the EEG may be normal because of the attenuation of recordings from the scalp. A tremendous increase of abnormal electrical activity can be seen from electrodes placed directly on the cerebral cortex at the time of surgery, in contrast to simultaneous recordings from the scalp.

Activation techniques. Certain techniques may bring out abnormalities not previously evident or exaggerate abnormalities noted in the resting record.

Hyperventilation. A response to hyperventilation is abnormal if spikes are associated with paroxysmal series of slow activity (Figure 5, right side) or if a focal spike or focal slow wave pattern is evoked. Hyperventilation frequently evokes 3 per second spike and wave paroxysms of petit mal epilepsy. On the other hand, even an unusually prolonged series of high voltage slow activity during and after hyperventilation is of indeterminate significance.

Photic stimulation. The response to photic stimulation is considered abnormal if bilaterally synchronous or focal paroxysmal spike and slow wave activity is evoked, or if suppression of normal driving response occurs over one hemisphere. Brief paroxysmal series during photic stimulation may be of equivocal significance, but paroxysmal activity can be considered definitely abnormal if the response persists after the cessation of the photic stimuli (Figure 6B).

Metrazol activation. Metrazol activation, either with or without photic stimulation, is only of value in establishing a focal EEG abnormality, for the normal threshold of convulsibility may be unusually low and bilaterally synchronous paroxysmal activity may be evoked in normal as well as epileptic individuals. Metrazol activation is also of value in differentiating hysterical seizures from true epilepsy. The test can be used to precipitate a seizure and allow first hand observation under EEG control.

Intracarotid Amytal activation of the EEG. This technique is used in the study of patients prior to surgical resection of an epileptic focus. The test is valuable in establishing the side of cerebral dominance and in confirming the site of primary epileptogenic focus. Intracarotid Amytal injected in a patient who manifests bilateral seizure activity will cause obliteration

of that activity in both hemispheres if its primary site of origin is in the hemisphere ipsilateral to the injection, but only the epileptogenic activity on the side of injection will be obliterated if the primary focus is in the contralateral hemisphere.

Carotid compression. Carotid compression under EEG, electrocardiographic (ECG), and blood pressure controls may be helpful in establishing the site of major arterial stenosis or occlusion. Compression of a normal carotid artery in the presence of occlusion of the opposite carotid artery or disease of the vertebrobasilar arteries will usually evoke diffuse slow activity.

The EEG is useful in monitoring depth of anesthesia and could be used to greater advantage in cardiac or carotid surgery by noting changes in cerebral electrical activity while the patient is under general anesthesia.

Abnormal EEGs in "normal" people. What percentage of the normal population have abnormal EEGs? Most electroencephalographers agree on a figure of 10 to 15 per cent. The difference in statistics is due in large part to differences in interpretation of those EEGs which lie on the borderline of normal, i.e., diffuse slightly fast or diffuse slightly slow activity. Those so-called "normal" people who have abnormal EEGs, probably experienced, at some time in their lives, a subclinical disease or injury that caused persistent cerebral electrical changes (for example, birth trauma without obvious signs or encephalitis manifested by no more than headache and "a common cold").

Artifacts. It may appear to be a simple task to analyze the EEG with respect to its wave form, frequency, and voltage, relating these factors as they occur in rhythms over the two hemispheres. Unfortunately, because of the great amplification of electrical activity, artifacts are frequently present and form a major pitfall in the interpretation of the EEG. Examples of the latter are seen in Figures 15 and 16. Muscle contraction and movement cause a great variety of artifacts (Figure 15A) but are usually easily distinguished. Swallowing may cause a paroxysmal burst of spikes (Figure 15B). A defective electrode may cause focal spikes or focal slow activity (Figure 15C). ECG, when superimposed on the EEG, may sometimes simulate spike and wave patterns (Figure 16A). The almost imperceptible tremor of parkinsonism may cause paroxysmal spike and slow wave artifact (Figure 16B). Eye movement is a common source of artifact that need not be limited to the bifrontal areas (Figure 3A).

In summary, except in epilepsy, the EEG is usually not a definitive test, but then, few tests are. The EEG should be used as any other laboratory tool and judged only in association with all other factors in the clinical evaluation of the patient in order to establish as wide a base as possible for appropriate diagnosis and treatment.

The EEG in psychiatry. It is too much to ask that the relatively crude methods used in recording the sum effect of the electrical activity of millions of neurones can measure psychological phenomena that represent the highest integrative function of the brain. (We know, in fact, that the normal EEG patterns are best recorded when the cortex is least integrated, i.e., when the individual is resting comfortably with his eyes closed and his mind unstimulated. Activation of high cerebral function will tend to disrupt the well formed EEG pattern.)

EEG is of relatively little aid to the clinical psychiatrist, for specific EEG abnormalities do not

FIGURE 15. Artifacts. *A*, A combination of movement and muscle artifact manifested by high voltage irregular slow waves and very fast activity, respectively. *B*, swallowing artifact manifested by paroxysmal series of spikes followed by lower voltage series of very rapid activity. *C*, right ear electrode artifact manifested by a random irregular slow wave, a random spike, and an irregular spike and slow wave complex.

FIGURE 16. *A*, ECG spike artifact superimposed upon the normal high voltage slow activity evoked by hyperventilation in a child causes an irregular spike and slow wave pattern. *B*, A burst of spike and slow wave activity occurring at a rate of 5 to 6 per second, seen in a patient with parkinsonism and almost imperceptible tremor.

correlate with specific emotional illnesses. The EEG is abnormal in a larger percentage of patients with emotional illness than in the normal population, but a consistent type of abnormality is not present.

Intelligence. There is no correlation between the EEG and normal or above normal intelligence. In those people with intellectual deficits, EEG abnormalities are much higher than in the normal population. The most common EEG patterns in individuals with subnormal intelligence reveal a relatively small

amount of α rhythm and diffuse slow activity; fast or paroxysmal abnormalities may also be present.

Personality. Passive, dependent, submissive individuals often show relatively high amplitude α rhythm in a large percentage of the record. Aggressive, competitive individuals, on the other hand, often have EEGs of low amplitude poorly formed α rhythm (this is thought to be more often the case in females than males).

Behavior or personality disorders. Considerable difference of opinion exists with regard to the EEG characteristics of individuals with behavior disorders. The European schools stress EEG evidence of immaturity, whereas Americans, led by Gibbs, stress the association of EEGs with 14 and 6 per second spike patterns.

Behavioral disorders of childhood. Children with episodic visceral complaints often have accompanying psychological symptoms, and frequently their EEGs are abnormal. Intermittent headache or dizziness; intermittent abdominal pain, sometimes associated with generalized weakness; pallor; and excessive perspiration or temperature alteration may be manifestations of an autonomic seizure. The behavioral disturbances most likely to reveal EEG abnormalities are those of the aggressive types.

The EEG patterns associated with behavioral disorders or the episodic symptoms described above are not consistent, for virtually every type of EEG abnormality has been reported. Paroxysmal EEG abnormality is commonly associated with episodic visceral phenomena, and the latter may then be considered a manifestation of abdominal epilepsy or other autonomic convulsive disorder (Figure 10B). Fifty to 60 per cent of children with behavioral disorders reveal immature records manifested by diffuse slow activity, maximal over the occipital and temporal lobes.

The significance of the 14 and 6 per second positive spike pattern (Figure 10A) is still in doubt. This activity, because it occurs most often while recording from the temporal areas during drowsiness or light sleep, is seldom found in some EEG laboratories. When the 14 and 6 per second positive spike pattern was first reported in 1951, some doubted its existence as a specific entity. More recently, the pendulum has swung in the opposite direction, for this pattern is now known to occur in 50 per cent of normal adolescents. Fourteen and 6 per second positive spikes are one of the most common electroencephalographic correlates of behavioral disorders and episodic visceral phenomena during childhood, and many believe that this electrical activity represents a minor seizure phenomenon. Symptomatic improvement of patients treated with anticonvulsants has been cited in support of the epileptogenic mechanism, but well controlled studies have not been performed. Heredity plays some part in the 14 and 6 per second spike pattern of children, for abnormalities in the EEG are seen in a greater percentage of these children's parents than in the normal population.

Personality disorders in adults. Adults in this large category, particularly those with aggressive characteristics, often reveal prominent temporocentral θ activity and/or 3 to 5 per second posterior temporo-occipital slow activity over one or both hemispheres. Increase in slow wave activity occurs during hyperventilation. This group has a much higher percentage of 14 and 6 per second positive spikes than is seen in the normal population. When spikes or other abnormal activities are seen from the anterior temporal lobe in adults with personality disorders, it is very likely that many of these patients have psychomotor epilepsy or behavioral disturbances due to mechanisms operative in psychomotor epilepsy. The EEG of criminals is often normal, but, when abnormal, the patterns are similar to those described above.

Psychoneuroses. Anxiety causes a decrease in α rhythm and increase in low voltage fast activity (Figure 3B), especially over the central areas. Maturational defects in the EEG, such as increased percentage of bitemporal θ activity, may also be present.

Those individuals who manifest obsessional phenomena and

patients with psychosomatic complaints reveal EEG characteristics no different from those of the normal population.

Patients with hysteria often have immature records. Reports of the effects upon the EEG when affected parts of hysterical individuals (or of patients under hypnosis) are being stimulated are not consistent. Most often the cerebral electrical activity of these patients will appear to react exactly the same as that of normal individuals. There are isolated reports, however, that indicate a true physiological block of sensory pathways. Thus, evoked potentials recorded in the EEG (using a photoelectronic averaging technique) after painful stimulation of the normal extremity may not be present when the hysterically analgesic extremity is stimulated, until the patient is placed under light general anesthesia. (Similarly, when blindness is suggested to the patient under hypnosis, the α rhythm of the EEG may not be blocked on visual stimulation.)

Nonorganic psychoses

Affective psychoses. Individuals with manic depressive psychosis reveal a somewhat greater percentage of abnormal EEGs than in the general population, especially β abnormalities. The α frequency is often increased in those who are predominantly manic and decreased in those who are predominantly depressed. Reactive depression appears to be more often associated with temporal lobe abnormalities than would be expected on the basis of chance.

Schizophrenia. It is not surprising that the reports of EEG characteristics in this disorder are as variable as is the definition of this syndrome. Certainly a consistent pattern is not present. The majority of these patients have normal EEGs, but the percentage of abnormal EEGs in patients with schizophrenia is two or three times that of the normal population. Abnormality in the EEG is more likely to be present when there is a family history of psychosis or when the onset of the disease is early, the duration long, and the severity great. EEG abnormalities are most often seen in catatonies, least often in paranoids. In schizophrenics, α rhythm may not respond to visual or emotional stimuli. Beta activity and paroxysmal abnormalities are more frequent than in the normal population. Low voltage slow activity is often seen in catatonic stupor. Paroxysmal patterns are seen more often in catatonies than in other forms of schizophrenia. These paroxysmal activities are maximal over the posterior cerebrum, faster than 4 per second, and are of lower voltage than the patterns characteristic of epilepsy.

Gibbs reported that certain complexes, called B-type mittens (see above), correlate with psychosis. These activities may be very difficult or impossible to distinguish from other mitten forms or from other sharp and slow wave complexes. Gibbs found that 42 per cent of those patients who had psychosis with epilepsy showed a B mitten pattern in their EEG and 35 per cent of those individuals who had psychosis without epilepsy revealed this pattern. Of the latter, the majority were schizophrenic. According to Gibbs, when the B mitten is found in an EEG there is a 73 per cent presumption that the individual is psychotic.

Organic psychoses. The EEG abnormality corresponds to the nature of the underlying lesion in the organic psychoses.

Patients with senile dementia reveal a slowing of the α frequency and a decreased percentage of α rhythm. (These are normal manifestations of the aging process.) In addition, diffuse θ or, less often, diffuse δ activity may be present. The severity of dementia does not necessarily correlate with the severity of the EEG abnormality, for in some cases rather severe dementia may be present while the EEG remains within the range of normal. In Alzheimer's disease and other forms of dementia, on the other hand, the EEGs are almost always abnormal and reveal diffuse slow activity, often with focal components.

The EEG is helpful in establishing the diagnosis of psychosis secondary to drug or toxic encephalopathy (see Section 10.3) and psychosis with epilepsy (see Section 10.4).

Additional techniques of EEG study

The sedation threshold. This is the amount of sodium Amytal required to produce a maximum degree of fast activity in the EEG. Unfortunately, there is not a sharp end point, and the degree of variation is too great for most diagnostic purposes. The sedation threshold is highest in patients with anxiety states, but it is also high in obsessive-compulsive individuals, those with reactive depression, and chronic schizophrenics. The sedation threshold is lower than normal in organic psychoses. It has its greatest practical value in differentiating endogenous depression, which has an unusually low sedation threshold in spite of agitation, from reactive depression with its high threshold.

Photic Metrazol stimulation. This form of stimulation, at some stage, will evoke a paroxysmal response in every individual, but the threshold is often unusually low in schizophrenics as well as epileptics.

Depth electrode studies. Such studies have shed some light on the physiological substrate of emotion. Spike discharges and slow wave activity in the septal region, the hippocampus, and the amygdala have been recorded in patients with schizophrenia and other psychoses. Bilateral bursts of high voltage 2 to 5 per second slow activity have been noted from deep ventromedial frontal areas in psychotic patients, but most of these patients had been tested after electric shock therapy. High voltage fast spindles have been recorded from the hippocampus of patients during periods of strong emotion.

Psychotropic drug evaluation. Psychotropic agents alter the frequency, synchronization, and response to stimulation of the EEG, although usually only to slight degrees. Electronic frequency analysis reveals different patterns for different drugs. This technique has been advocated for comparative drug studies or for screening new compounds, but it is not yet practical.

Electroconvulsive therapy. The severity of the EEG abnormality after electroconvulsive therapy (ECT) is a highly individual factor. (After the first electric shock there is usually quick return of the EEG to normal, but slow activity usually persists after several treatments. The EEG returns to normal after days, weeks, or months, or it may never return to normal. Even with the latter circumstance, other clinical evidence of organic cerebral disease usually is not present. The number and frequency of shock treatments are important factors in the severity of EEG abnormality, but there are too many variables to correlate these features with the rapidity of disappearance of slow activity. A major factor is the underlying cerebrovascular status of the patient. The slow activity after electroconvulsive therapy is presumed to be due to the same mechanism as that following seizures of other origin, i.e., neuronal loss or dysfunction due to failure of the vascular supply to meet the increased metabolic demands of the electrically hyperactive discharging brain.)

There is some evidence that organic changes manifested in part by an abnormal EEG must occur for success of ECT; when slow activity in the EEG fails to persist or is relatively slight, the outcome of the therapy is often unfavorable. Delta slow wave activity may be revealed at an early stage in the course of therapy by intravenous barbiturate-induced sleep records 3 to 4 hours after ECT. This method has been calibrated and used in determining the effectiveness of such treatment.

Examination of the Spinal Fluid

Significant complications of a lumbar puncture are rare. Papilledema and other evidence of increased intracranial pressure, especially with a mass lesion in the posterior fossa, are the major contraindications for this procedure. Sudden change in intracranial pressure may occur at the time of a spinal tap in the

presence of increased intracranial pressure. This change may cause herniation of the hippocampal gyrus through the incisura of the tentorium of the cerebellum with resultant compression of the upper brain stem, or it may cause shift and associated compression of the medulla and tonsils of the cerebellum into the foramen magnum. These complications are grave and their possible occurrence must be weighed against the potential benefits of a lumbar puncture in the presence of increased intracranial pressure.

The spinal tap is performed by inserting a needle into the spinal canal below the spinal cord which ends at vertebral level L1 or L2. Usually the tap is made at the level of the iliac crest corresponding to the inter-space of L3-4 or L4-5.

The initial spinal fluid pressure must always be measured with the patient horizontal and relaxed. Pressure over 180 to 200 mm. is elevated. Causes of increased intracranial pressure have been discussed above. Manometries as tested by compression of the jugular veins should always be performed when a spinal lesion is suspected but must not be performed when there is suspicion of an intracranial lesion.

The color and clarity of cerebrospinal fluid is normally indistinguishable from water, with which it should be compared. Bloody spinal fluid may be due to a traumatic lumbar puncture. If this is so, the percentage of blood in the spinal fluid will decrease in successive collecting test tubes, the red blood cells will not be crenated, and the supernatant spinal fluid after centrifugation will be clear. Blood in the spinal fluid is usually due to a subarachnoid hemorrhage or, less commonly, to an intracerebral hemorrhage that has ruptured into the ventricles or out to the subarachnoid space. Cerebral trauma, especially a subdural hematoma, may be associated with blood in the spinal fluid. Xanthochromic spinal fluid is seen as the residual pigment of blood after a subarachnoid hemorrhage, or with a subdural hematoma, but also may be evident when the spinal fluid protein is unusually high. Severe jaundice may cause a yellow discoloration of the spinal fluid. Turbid cerebrospinal fluid may be due to meningitis, a slight amount of blood in the spinal fluid, or a highly elevated protein content.

Spinal fluid should routinely be examined for both red and white cells, serology, protein, and sugar. An elevated white blood cell count, i.e., over 6 lymphocytes per cubic millimeter, is indicative of inflammation or irritation of the meninges. If the cell count is elevated, the spinal fluid should be smeared and stained, as well as cultured, for infecting organisms. A low grade infection such as central nervous system syphilis or aseptic meningeal irritation, e.g., a brain tumor near the meninges, may be manifested by 5 to 50 white blood cells, especially lymphocytes, per cubic millimeter. Chronic meningitis causes an elevation of white blood cells, predominantly lymphocytes, in the range of 50 to 500 per cubic millimeter. An acute purulent meningitis is usually associated with a pleocytosis of 1,000 to 15,000 white blood cells per cubic millimeter, predominantly (90 per cent) polymorphonuclear leukocytes. Tumor or yeast cells may resemble white blood cells in the routine white cell count of the spinal fluid. If a search for exfoliative tumor cells is to be made, a large amount of spinal fluid must be centrifuged.

Protein elevation of the spinal fluid, i.e., over 50 mg. per 100 ml., may be seen in any organic neurological disease. If the spinal tap has been traumatic, the amount of protein added to the spinal fluid by the blood can be roughly calculated by subtracting 1 mg. per cent of protein for every 750 red blood cells per cubic millimeter. As a rule of thumb, an elevation of protein over 100 mg. per cent is much more indicative of cerebral neoplasm than of a cerebrovascular lesion. Fluid drawn below a spinal block usually contains protein elevated beyond 100 mg.

per cent, and the cerebrospinal fluid of meningitis may reveal similar findings.

The sugar content of spinal fluid is normally 50 to 65 mg. per cent, i.e., one half to two thirds, of the blood sugar drawn at the time of the spinal tap. Spinal fluid sugar below 40 mg. per cent is definitely abnormal and is found in meningitis of bacterial or fungal origin, but it may sometimes occur in non-infectious diseases, e.g., meningeal carcinomatosis and sarcoidosis.

Positive spinal fluid serology is indicative of active central nervous system syphilis if it is accompanied by an elevated white cell count and elevated protein in the cerebrospinal fluid. The colloidal gold test is performed only if central nervous system lues is suspected. As an aid in the diagnosis of multiple sclerosis, the latter test has been supplanted by the quantitative determination of the γ -globulin content of the spinal fluid. In multiple sclerosis the cerebrospinal fluid γ -globulin is usually elevated, i.e., beyond 12 to 15 per cent of the total protein. Evaluation of spinal fluid chlorides is of little value, although sometimes chlorides are low (below 120 milliequivalents per liter) in tuberculous meningitis.

Roentgenograms of the Skull

Routine roentgenograms of the skull should include a posterior-anterior view, lateral view, and Towne's view (anterior-posterior projection with the chin flexed on the chest). Other special views, stereoscopy, or laminagraphy may be necessary to visualize specific structures such as the internal acoustic meati, the optic foramina, or the base of the skull.

Normal landmarks. In the skull films one studies the appearance of those normal landmarks as the sella turcica, the petrous pyramids, and the calcified pineal gland. The shape and integrity of the skull are observed for evidence of developmental anomalies or fracture. Both abnormal and normal calcifications must be recognized as well as evidence of erosion or exostoses.

Calcifications. Normal or benign calcifications include those within the dura, especially the falx cerebri, the pineal body, the choroid plexus, the petroclinoid ligament, and the habenula. Abnormal calcification may be found in certain tumors. Calcification can be roentgenographically visualized in 50 to 60 per cent of oligodendrogliomas, 25 per cent of ependymomas, 15 to 20 per cent of meningiomas, and 70 per cent of craniopharyngiomas. Teratomas and, rarely, astrocytomas may also present calcifications. The most common vascular lesion is atherosclerosis, and calcification is often seen, especially in the siphon of the internal carotid artery. Calcifications may be visualized within aneurysms, chronic subdural or intracerebral hematomas, and underlying the angioma of Sturge-Weber's disease. Those infectious processes which may reveal multiple calcifications include toxoplasmosis, cytomegalic inclusion body encephalitis, and cysticercosis. Calcification is often noted within a tuberculoma or other chronic abscess. An uncommon disease in which calcifications may be seen is tuberous sclerosis. Sometimes the basal ganglia calcify either secondary to parathyroid disease or from an unknown cause.

Erosion. Increased intracranial pressure may be manifested in roentgenograms of the skull by erosion of the clinoid processes and dorsum sellae, increased convolutional markings, and, in children, separation of the sutures. Large channels due to increased vascular markings may lead to an area occupied by a meningioma. Enlarged foramina of cranial nerves are often indicative of associated tumor. The most common example is the enlarged internal acoustic meatus due to an acoustic neuroma. Metastases to the skull, most often from carcinoma of the breast, commonly cause erosion.

Exostoses. A localized area of exostosis is often seen overlying a meningioma. Hyperostosis frontalis interna is an insigni-

ficant finding, in spite of syndromes associated with it in the past.

Radioisotopic Encephalography (Brain Scan)

Abnormal tissue within the head, in contrast to normal brain tissue, tends to retain radioisotopic compounds. This effect is presumably due to the breakdown of the blood-brain barrier associated with organic brain disease. By means of scanning equipment, markedly improved in recent years, the γ energies emitted by the radioisotope retained in a lesion can be mapped on X-ray film (photoscan) as well as automatically mapped by dots on paper.

The scanning equipment, a directional γ ray detector, passes along a 0.5-cm. spaced line at a rate of 20 cm. per minute in a pattern of parallel sweeps until the entire plane of the head (anterior, posterior, or lateral) is covered. The radioisotope (e.g., 1 millicurie of chlormerodrin, labeled with mercury-197 (half-life 3 days)) is intravenously injected 2 to 4 hours prior to the scanning. The interval between injection and scanning allows the kidneys to clear the radioisotope from the blood and thus diminish the background radioactivity in the blood stream of the head. Because this background radioactivity is particularly prevalent over dense muscles and draining vascular structures, it often obscures lesions of the posterior fossa, sella turcica or sphenoid ridge. In cases of suspected posterior fossa lesion, a 24-hr. interval between injection of radioisotope and scanning is sometimes advisable to allow more complete clearing of the radioisotope from the blood. On the other hand, a short, 15- to 45-min., interval is used when searching for a suspected vascular malformation. The brain scan is most consistently positive in mass lesions (neoplasms, abscesses, hematomas) but is also positive in arteriovenous malformations and in most cases of cerebral infarction. The brain scan is as accurate in localizing a lesion as any test now available, for the radiographic abnormality is seen within the lesion rather than inferred by displacement of vessels or ventricles, as is often the case in angiography and pneumography. Brain scans, on the other hand, are frequently negative when the lesion is small, i.e., less than 3 cm. in diameter, or avascular (such as a cyst), or obscured by muscle mass or confluence of blood vessels. A major drawback of brain scanning is that one cannot definitely differentiate mass lesions from other abnormal tissue, such as an infarct. Another deficiency of the test is the need for the patient to remain quiet at least $\frac{1}{2}$ hr., the time required for scanning the head in one plane. The test is harmless in adults but, since the radioisotope is excreted by the kidneys, unknown long term renal effects might occur in children. Further improvement in scanning equipment and newer radioactive compounds may make this test even more valuable in the future than it is at the present.

Echoencephalography

The recorded echo of a very high frequency sound (ultrasound) is used to measure the location of intracerebral structures.

The "A" scan records the location of midline structures (falx cerebri, third ventricle, septum pellicidum) of the brain. Shift of midline structures has the same significance as shift of the pineal gland and most often indicates a mass lesion on the side opposite the direction of shift. Since the procedure is harmless and painless, it can be used as a screening procedure in cases of suspected intracranial mass lesion. It is particularly helpful in those patients who do not have localizing neurological signs, as may be the case in comatose individuals. The "B" scan roughly outlines the ventricles or an intracerebral mass

that has a density different from that of the cerebral parenchyma. The equipment and technique required for the "B" scan have not yet been perfected, but it is useful in establishing the diagnosis of hydrocephalus and may be of aid in localizing brain tumors.

Rheoencephalography

Rheoencephalography is a method of graphically recording alteration in electrical conductivity of brain tissue as affected by changes in the cerebral circulation.

Different tissues offer varying resistances to the passage of alternating current, and conductivity improves when the amount of blood in a given tissue volume increases, as during each arterial pulse wave. This procedure simultaneously records pulse waves in each cerebral hemisphere and, in the future, might prove to be a useful method of monitoring certain intracerebral vascular dynamics. The technique and equipment are not sufficiently refined to yield practical results at this time.

Pneumoencephalography and Ventriculography

Roentgenographic visualization of areas normally containing cerebrospinal fluid can be attained when air is substituted for cerebrospinal fluid.

Pneumoencephalography is accomplished by the injection of air, usually 30 to 75 cc., via the route of a lumbar puncture, performed with the patient seated. Air is allowed to rise into the head and fill the ventricles, the subarachnoid spaces of the basal cisterns, and the sulci over the convexity of the brain. Pneumoencephalography is, of course, contraindicated in patients with increased intracranial pressure. In the latter circumstance, ventriculography is performed by the direct instillation of air into a lateral ventricle through a burr hole in the posterior parietal area of the skull. Serious complications of pneumoencephalography are rare (less than 1 per cent). They are due to shift and herniation of the brain (see above) or to precipitation of cerebrovascular lesions.

Pneumoencephalography is well suited to the evaluation of congenital hydrocephalus, sometimes manifesting hugely dilated ventricles with only a small rim of cerebral cortex. Atrophic brain diseases are also best studied by means of pneumoencephalography. Focal atrophy, as in post-traumatic epilepsy, is seen as large air-filled sulci. Diffuse cerebral degeneration, e.g., Alzheimer's disease, is manifested by dilated ventricles and scattered areas of widened sulci. In tuberous sclerosis small multiple nodules along the walls of moderately dilated ventricles are seen. A mass, i.e., neoplasm, hematoma, abscess, or cyst, deforms or displaces the walls of the adjacent ventricles. The sulci of the cerebral hemisphere containing a mass are usually less well filled with air than those of the normal side. If the mass is near midline structures, obstruction to the outflow of cerebrospinal fluid results in ventricular dilation.

Cerebral Angiography

After the introduction of radio-opaque solutions (meglumine iothalamate (Conray) or diatrizoate sodium (Hypaque)) into arteries supplying the brain, arteries and veins can be seen in serial roentgenograms.

The opaque solutions are injected percutaneously into the common carotid artery in order to visualize vessels of the ipsilateral cerebral hemisphere, as supplied by the internal carotid, anterior cerebral, and middle cerebral arteries; and into the vertebral artery to visualize the blood supply of the brain stem, cerebellum, and posterior cerebrum via the vertebral, basilar, and posterior cerebral arteries. Right brachial arteriography allows visualization of both the right carotid

arterial tree and the right vertebrobasilar circulation. Left brachial arteriography opacifies the left vertebral and basilar arteries. Aortic arch arteriography via catheterization of a femoral or axillary artery permits visualization of all arteries leading to the brain, but when a large number of vessels are simultaneously opacified there is less detail in the roentgenograms. Complications of arteriography occur in 2 to 4 per cent of patients and are manifested primarily by ischemia or infarction of the brain with convulsions, focal signs, or (very rarely) death. These events are caused by inadvertent embolic phenomena (air or calcific plaques), manual or hemorrhagic occlusion of the punctured artery, prolonged carotid sinus effect, or idiosyncratic or allergic reaction of the nervous tissue to the injected contrast material; hemorrhage from the punctured artery may also occur. As a rule angiography is performed when a focal lesion is suspected (except when the focal lesion is thought to be atrophic), or when an aneurysm or vascular malformation is sought. Inability to determine clinically the presence or site of a focal lesion would lead to pneumoencephalography either before or instead of angiography. Neoplasms may be angiographically demonstrated by the displacement of adjacent blood vessels or the presence of a "tumor stain." The latter is seen as retained contrast material in a zone of new or abnormal vessels within the tumor. Glioblastomas and meningiomas usually have characteristic tumor stains. While a hematoma displaces vessels in a manner exactly like that of a neoplasm, the mass of hematoma appears avascular. A subdural or epidural hematoma displaces the cortical vessels from the inner table of the skull and is best seen in the posteroanterior views. Occlusion or stenosis of major arteries can be angiographically demonstrated. Prior to carotid endarterectomy, both right and left carotid and vertebral arteries must be visualized. This can best be accomplished by a single injection of contrast material into the aortic arch.

Myelography

The configuration of the spinal subarachnoid space can be visualized in roentgenograms after 6 to 12 cc. of radio-opaque liquid (iophandylate (Pantopaque)) are injected via a lumbar puncture.

The radio-opaque solution, heavier than spinal fluid, is maneuvered through the spinal canal by tilting the patient on the X-ray table under fluoroscopic control. Mass lesions (neoplasms and herniated intervertebral discs) are precisely located by their indentation of the radio-opaque column. Less common causes of complete or partial block of the subarachnoid space as visualized myelographically include arachnoiditis, spinal abscesses, and diseased vertebrae. Vascular malformations of the cord may also be recognized by a typical configuration within the Pantopaque column. The spinal needle used for injection of the contrast material is maintained in place throughout the procedure, so that at the completion of the test the Pantopaque may be removed. Complications of myelography are extremely rare and consist of arachnoiditis.

Electrodiagnosis

There are several procedures most helpful in confirming the diagnosis of lower motor neuron disease or myopathy.

Testing the responses of muscle to stimulation at motor points by direct galvanic current or by faradic tetanizing current was the chief electrodiagnostic method until the adaptation of the cathode ray oscilloscope. A sluggish response to galvanic stimulation or a decreased or absent response to faradic stimulation is indicative of denervation.

Nerve conduction velocity. This is determined with the use of two electrodes placed over the skin of the nerve and muscle to be tested. The time, as a measure of distance on the cathode

ray oscilloscope, required for the impulse to travel between the stimulating proximal electrode and the distal recording electrode is tabulated. The speed of conduction between the known distance of the two electrodes is then calculated. Normal conduction velocities range from 40 to 50 m. per second for the ulnar, median, and peroneal nerves. The conduction time through a simple, monosynaptic reflex arc (similar to that of the knee jerk) can be measured and recorded as the H reflex. Motor diseases of the central nervous system influence the reactivity of the lower motor neurone and may be evaluated by changes in the H reflex.

The electromyogram (EMG). The EMG is a record of electrical activity transmitted from muscle by a needle electrode to a cathode ray oscilloscope and a loudspeaker for purposes of visual and auditory evaluations. A normal muscle is electrically silent at rest. During contraction, normal action potentials are manifested by fast, moderate voltage, well modulated bursts of activity. Ten to 20 days after nerve injury, evidence of denervation can be found. A partially denervated muscle produces complex polyphasic arrhythmic, high voltage potentials during contraction. With total denervation, spikes of low voltage fast random potentials (fibrillations) are noted at rest; these sound like the drops of rain on a tin roof. Resting denervated muscle may also give rise to spontaneous brief motor unit contractions (fasciculations), seen as high voltage complex potentials. Tests of a patient with muscular atrophy due to disease of the anterior horn cells in the spinal cord reveal fibrillation potentials with normal nerve conduction velocity. These studies in an individual with lower motor neuron disease of more peripheral origin show delayed conduction velocity as well as fibrillation potentials. In muscular dystrophy, electrical activity during muscle contraction is faster and of lower voltage than normal action potentials. The EMG of a patient with myositis may reveal activities indistinguishable from fibrillations, but, in addition, dystrophic electrical patterns are seen. The contraction of myotonic muscle or stimulation of this muscle by needle insertion is manifested by prolonged electrical activity that slowly fades away (decreases in amplitude); this activity sounds like a dive bomber. In myasthenic patients, abnormal fatigability of muscles activated by repetitive electrical stimuli is seen by the rapidly progressive decrease in amplitude of electrical activity. Hysterical weakness is suspected when irregular contractions of varying strengths are poorly sustained.

Cystometric Examination

In the cystometric examination, intravesicular pressures, transmitted to a manometer attached to a catheter, are recorded after specific amounts of saline have been introduced into the urinary bladder. The patient's sensations of fullness and desire to void are also noted.

Normally, a powerful voiding contraction occurs at a volume of 400 to 500 cc. A spastic (reflex) bladder, as may occur with a lesion of the pyramidal tracts in the spinal cord, produces a relatively high pressure with a small volume. An atonic bladder, associated with lower motor neuron disease or a lesion of sensory pathways, reveals relatively low pressure at a large capacity. A complete, usually traumatic, lesion of the conus medullaris or adjacent structures often results in autonomous bladder activity with muscle tone partially preserved. The demented, incontinent patient usually has normal cystometric responses, whereas urinary retention of psychological origin often presents evidence of an atonic bladder.

10.2 ANATOMY AND PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM

SEYMOUR SOLOMON, M.D.

Localization of Function and Signs of Focal Disease

Many areas of the brain are clinically "silent"; i.e., recognizable symptoms or signs need not result from a lesion of these parts. The following sites are associated with specific functions and, when diseased, specific signs occur. The physiology of these areas, as related to psychological phenomena, is only briefly noted, for this topic has been discussed in detail elsewhere in this text.

The Cerebral Cortex

A discussion of the functions of the cerebral cortex has been presented in another section (Section 2.9). A chart of cerebral functions and a drawing of the cytoarchitectural map of the cortex after Brodmann appear following Section 2.9. It must be emphasized that the specific areas described are neither anatomically nor physiologically sharply demarcated.

Frontal lobe. The frontal lobe is anterior to the central sulcus, or Rolandic fissure.

Motor area. This area is in the most posterior portion of the frontal lobe, and occupies the precentral convolution. The motor area contains the greatest number of Betz pyramidal cells and gives rise to corticobulbar and corticospinal pathways. Impulses from this area initiate volitional movement on the opposite side of the body. The lower extremity is represented over the medial portion of the contralateral cortex, and the remainder of the body is represented over the adjoining convexity. Those parts requiring greater complexity of function, such as the fingers, are represented over a disproportionately wide area. Loss of function in this area results in contralateral weakness or paralysis. In monkeys, apes and perhaps humans, the paresis or palsy is first flaccid and later spastic.

Premotor area. Anterior to the motor area, the premotor area controls motor function of the opposite parts of the body paralleling the functions of the motor area. The contralateral weakness or paralysis associated with a lesion in this area is spastic in primates.

Frontal motor eye field. This area is anterior to the premotor area and is the center of volitional control of conjugate eye movement. A destructive lesion in this field is associated with initial but transient deviation of the eyes to the side of the lesion and palsy of conjugate gaze to the opposite side, whereas an irritative lesion causes conjugate gaze toward the opposite side.

Motor speech area (Broca's area). This area is located over the inferior aspects of the motor and premotor areas in the dominant hemisphere. It is the center for expressive speech. A lesion in this area is often associated with expressive aphasia, but aphasic phenomena are even less well localized in the cortex than other signs (see Section 10.1).

Less well defined areas within the frontal lobe. A transitional area between the motor and premotor zones is believed to be inhibitory in its action, and lesions affecting this area are primarily responsible for contralateral spasticity.

In or about the middle frontal convolution is the origin of fibers giving rise to the corticopontocerebellar tract. This area permits smooth voluntary and automatic skeletal muscle movement. Loss of function is manifested by contralateral ataxia and other "cerebellar" signs (see Section 10.1).

There are intimate but poorly defined connections between the frontal lobe and basal ganglia. With cerebellar centers, these connections elaborate voluntary and automatic movement. Cortical lesions do not usually cause basal ganglion symptoms because the cortical connections are too diffuse.

Frontal association areas or the prefrontal lobe. These zones are anterior to the motor and premotor areas. In this most anterior portion of the frontal lobe, neurons are interconnected with sensory areas of the cortex. In addition, connections, predominantly afferent, are made with the thalamus, and predominantly efferent impulses are sent to the hypothalamus. The prefrontal lobe governs higher intellectual functions (judgment, reasoning, abstract thinking) and restrains emotional impulses. Associations take place which allow appropriate complex responses to the environment; here is the highest level of motor integration. It is in this area that psychomotor activity is initiated. Lesions in this area may result in the mental and emotional symptoms described below.

Parietal lobe. The parietal lobe is posterior to the Rolandic fissure.

Primary sensory area. This area includes the postcentral gyrus and immediately adjacent areas. It receives and identifies somatic sensory stimuli, particularly touch and position sensations, relayed from the nucleus ventralis posterolateralis and posteromedialis of the lateral nuclei of the thalamus. The pattern of cortical representation very roughly corresponds to that of the motor cortex. A lesion in this area is associated with contralateral somatic sensory impairment but not complete analgesia or anesthesia.

Sensory association area. This area is located posterior to the primary sensory area. It synthesizes and elaborates somatic sensory impulses and permits stereognosis.

Other parietal areas. The area superior and posterior to the primary sensory and association areas has to do with discrimination of fine grades of somatic sensation, rather than simple appreciation. This area is also associated with stereognosis. In addition other complex perceptual functions are carried out.

Lesions of this area, as well as the sensory association area, frequently result in only slight contralateral sensory impairment or astereognosis. Inattention to stimuli (extinction of the contralateral stimulus during bilateral simultaneous stimulation) is often noted with these lesions. Sometimes trophic changes occur in the contralateral extremities, particularly the upper extremity.

The area inferior and posterior to the primary sensory and association areas contains the angular and supramarginal gyri. In this zone there occurs integration of visual and auditory stimuli with somatic sensations. A lesion in this area of the dominant hemisphere may be associated with aphasic phenomena, especially receptive dysphasia, dysgraphia, or dyslexia.

Defect in body scheme may occur. Gerstmann's syndrome (agraphia, acalculia, finger agnosia, right-left disorientation) may also be seen with lesions here, but this syndrome, as with aphasic symptoms, cannot be localized with consistency. See below for agnostic, apraxic, and aphasic phenomena as related to other mental symptoms. (A deep parietal lobe lesion may affect the optic radiations and cause contralateral homonymous inferior quadrantic or hemianopic visual field defects.)

Occipital lobe. The occipital lobe is the posterior tip of the cerebrum.

Primary visual receptive area. This area (Brodman's area 17) is located along the lips of the calcarine fissure on the medial aspect of the occipital lobe and extends to adjacent areas around the lateral surface. This zone receives impulses relayed by the lateral geniculate body from the ipsilateral half of each retina. There is virtually point-by-point representation of retinal segments in the calcarine cortex. A lesion in this area causes contralateral homonymous hemianopsia with macular sparing.

Parareceptive area. The parareceptive area (Brodman's area 18) is immediately adjacent to the above. In this area visual impulses are interpreted so that they may be recognized and identified. Perhaps memory engrams are stored here.

Preoccipital area. The preoccipital area (Brodman's area 19) is immediately adjacent to the parareceptive area. Area 19 connects the visual receptive and parareceptive areas with other parts of the cortex. Its function is complex and has to do with perception, recall, visual association, and orientation.

Areas 18 and 19 are also centers for optically induced reflexes, such as fixation, via corticofugal fibers to the midbrain, medial longitudinal fasciculus, and nuclei of the ocular nerves. Lesions of the parareceptive and preoccipital areas are associated with disturbed spatial orientation, impaired visual discrimination, visual agnosia, illusions, or hallucinations. Cortical blindness occurs with lesions of both occipital lobes (see below).

Temporal lobe. The temporal lobe is below and behind the lateral, Sylvian, fissure.

Auditory receptive area. This area is in the transverse temporal gyrus (Heschl's convolution) located on the posterior aspect of the superior temporal convolution. The auditory association area receives auditory impulses relayed by the medial geniculate body.

Auditory association area. This area is adjacent to the auditory receptive area but is poorly defined. It is in this zone that memory patterns for symbolic sounds are stored; here auditory impulses are differentiated and interpreted as words. This area may also receive vestibular impulses. A lesion of this area in the dominant hemisphere is associated with receptive aphasia (Wernicke's aphasia) and often dyslexia and dysgraphia as well.

Gustatory and olfactory areas. These areas are probably located deep in the Sylvian fissure and in the medial portions of the temporal lobe. They should be considered as part of the limbic system.

Unilateral lesions of the temporal lobe never cause auditory, gustatory, or olfactory impairment because these sensations have an extensive bilateral cerebral representation. (Subcortical lesions of the temporal lobe may affect optic radiations and cause contralateral homonymous superior quadrantanopsia.)

The functions of the temporal lobe are varied and complex. Although the physiology of memory is poorly understood, it is more closely associated with the temporal lobe than with any other area of the brain, and stimulation of the temporal lobe may evoke past memories. This lobe is probably associated with sexual function and other visceral phenomena (see below). The temporal lobe, as a major part of the limbic system, is intimately associated with psychological phenomena. Irritative lesions of the temporal lobes may cause psychomotor epilepsy or other mental and emotional symptoms (see below).

Subcortical Nuclear Structures (Figure 1)

Thalamus. The thalamus is the principal relay center for sensory pathways. These nuclei receive many different afferent

impulses and relay them to the cerebral cortex as well as to lower centers for further integration. The anterior nuclei of the thalamus are an important part of the limbic system and are linked closely with the cingulate gyrus. The medial nuclei are associated primarily with the prefrontal area of the brain. The lateral group of nuclei are further subdivided into an anterior and posterior portion. (The pulvinar may be considered the most distal aspect of the latter.) The anterior nuclei of this lateral group are concerned with connections between the motor cortex, basal ganglia, and cerebellum. The posterior nuclei of the lateral group (the nuclei ventralis posterolateralis and ventralis posteromedialis) receive sensory impulses from the body and face to be relayed to the parietal cortex. Visual and auditory impulses received by the pulvinar are relayed to visual and auditory association areas of the cortex. A lesion of the thalamus is associated with peculiar contralateral sensory phenomena, the thalamic syndrome (see Section 10.4).

Hypothalamus. The hypothalamus is the center controlling visceral functions. It governs the peripheral autonomic nervous system and, via its influence on the pituitary, regulates the endocrine glands. Thus it is responsible for maintaining normal homeostasis. Vital functions are controlled in this area: temperature stability; cardiovascular and respiratory activity; sleep cycle; metabolism of fat, carbohydrates, and protein; water and electrolyte balance; sphincter and sexual activity. The posterior and lateral nuclei of the hypothalamus are primarily sympathoadrenal in their function. The anterior and medial nuclei are mainly associated with parasympathetic activity.

The hypothalamus regulates neural and humoral mechanisms of emotional activity (see below) and may be regarded as an effector organ of emotional expression. The cerebral cortical representation of autonomic functions is poorly defined, but areas in the prefrontal lobe are known to be connected to the hypothalamus. These cortical autonomic centers probably act as inhibitory influences upon the more rudimentary visceral responses arising in the hypothalamus. As might be expected, a large variety of clinical syndromes are associated with lesions of the hypothalamus. Disease of the supraoptic nucleus causes diabetes insipidus. A lesion of the anterior nuclei, including the tuber cinereum, may be associated with prepubertal adiposity and genital dystrophy (Froelich's syndrome), or postpubertal amenorrhea and impotence. On the other hand, less well defined hypothalamic lesions may result in precocious puberty, and widespread disease of these nuclei is associated with emaciation. Lesions in the ventromedial nuclei of humans cause bulimia, and in lower animals the resultant voracious appetite is associated with savagery. Hyperthermia may follow a lesion of the anterior or ventromedial hypothalamic nuclei. Less commonly, hypothermia is associated with disease of the posterior nuclei. Disorders of sleep, especially hypersomnia, are seen with lesions of the posterior nuclei and adjacent structures of the upper brain stem. Convulsive disorders manifesting visceral phenomena may be due to dysfunction of the hypothalamus, and more common generalized seizures may arise in the hypothalamic portion of the centrencephalic system.

Basal ganglia. The basal ganglia consists primarily of the caudate, putamen, and globus pallidus; functionally related groups of neurones are the subthalamic nucleus, red nucleus, and substantia nigra. These structures are an essential part of efferent pathways and modify impulses from the motor cortex and interrelated cerebellum-thalamic relays. This complicated system elaborates and integrates complex voluntary motor activity to allow smooth actions. In addition, the basal ganglia take over motor skills that have become automatic. Lesions of the basal ganglia cause involuntary movements; alterations in muscle tone; and loss of associated, automatic, and expressive movements. See Section 10.1 for dyskinesias associated with disease of the basal ganglia.

Subcortical Fiber Bundles

Corpus callosum. The corpus callosum is the major commissural system of the brain connecting and facilitating inte-

Figure 1. Frontal section of brain, passing through mammillary bodies. (From Truex, R. C., and Carpenter, M. B. *Strong and Elwyn's Human Neuroanatomy*, ed. 5, p. 435. Williams & Wilkins, Baltimore, 1964.)

gration of functions of the two cerebral hemispheres. On the other hand, surgical section or congenital absence of the corpus callosum need not be associated with symptoms or signs.

Internal capsule. This is the major afferent and efferent pathway connecting the spinal cord and brain stem to the cerebral hemispheres. It also contains association fibers of the cerebellum, thalamus, and basal ganglia. Thus, a small lesion in this tightly packed area causes profound contralateral defects of motor, somatic sensory, and visual modalities.

Cerebellum

The afferent aspects of the cerebellum are primarily concerned with proprioceptive and vestibular impulses. Its efferent functions play an essential role in activity under control of the motor cortex. The cerebellum integrates and coordinates motor impulses, both voluntary and involuntary. Equilibrium is attained by cerebellar functions that maintain orientation of the individual in space and regulate muscle tone and posture. A lesion of the cerebellum results in ipsilateral incoordination of the trunk and extremities. See Section 10.1 for other signs associated with cerebellar disease.

Brain Stem

The brain stem consists of the medulla, pons, and midbrain. Efferent and afferent impulses pass through and are relayed in the brain stem. The cranial nerve nuclei are located in this vital area. Unilateral lesions of the brain stem are characterized by a combination of ipsilateral cranial nerve signs with contralateral long tract motor or sensory signs (see Section 10.3).

Reticular formation. This is a poorly demarcated group of neurones within the tegmentum of the brain stem. This complex network receives impulses from all parts of the peripheral and central nervous system and sends impulses to the spinal cord, thalamus, basal ganglia, and cerebral cortex. The reticular formation exerts both inhibitory and facilitatory influences upon the peripheral motor system. In the opposite direction its effect is that of maintaining the arousal or vigilant state and, by its influence on the threshold of the various stimuli, it has a large role in establishing the level of attention. It also takes part in regulating visceral, vascular, and endocrine activities. Lesions of the reticular formation may affect motor tone, state of consciousness, and any or all vital functions. Dysfunction of the reticular formation is probably associated with many psychological alterations, but these have yet to be documented.

Midbrain diencephalic area. The midbrain diencephalic area (the centrencephalic system) includes the ascending reticular formation, thalamus, hypothalamus, and adjacent structures.

It is thought to be the primary integrating system. Here the sensorimotor impulses of the occipital-parietal-central areas of the cortex are integrated with functions of the temporal (and probably frontal) cortex, producing those intellectual mechanisms essential to perception and memory.

Spinal Cord

The spinal cord is made up of long axones, carrying efferent and afferent impulses, surrounding a core of nerve cells. On cross section, the core of neurones appears as a grey "H" within the white matter, formed by myelin sheaths of the axones. The cell bodies of sensory neurones are located in the dorsal root ganglia. Nerve fibers carrying proprioception, vibration, and touch sensations ascend in the ipsilateral posterior column of the cord to nuclei in the brain stem. These sensory impulses are then relayed to the opposite side of the brain stem and up to the thalamus. Fibers carrying superficial pain and temperature terminate near the posterior horn of the grey "H" soon after entering the cord. These sensations are then relayed to the opposite lateral aspect of the cord and ascend to the thalamus in the lateral spinothalamic tract. Some fibers carrying touch sensation follow a similar course and form the ventral spinothalamic tract. The pyramidal, corticospinal tracts descend from the brain, decussate at the caudal end of the medulla, and take up the major portion of the lateral columns of the cord terminating at the anterior horn cells of the grey "H." Axons of these lower motor neurones then leave the cord, via the ventral roots, to innervate muscles. Short, intercalated neurones abound in the central grey matter and are integral parts of reflex arcs.

Disease of the posterior column causes ipsilateral loss of proprioception and vibration below the level of disease. A lesion of the lateral column results in ipsilateral upper motor neurone (spastic) paralysis and contralateral loss of pain and temperature sensitivity below the level of the lesion (Brown-Sequard syndrome). Disease affecting the anterior horn of the grey matter causes ipsilateral lower motor neurone (flaccid) palsy within the distribution of the diseased segment.

Mental and Emotional Syndromes Related to Site of Organic Disease

Mental and emotional symptoms have certain characteristics dependent upon the site of organic involvement. It must be stressed that all of the syndromes described below are both physiologically and anatomically interrelated.

Frontal lobe syndrome. The frontal lobe syndrome is associated with lesions of the prefrontal and basilar cortex of the brain, and the clinical features are most striking when the disease is bilateral. This condition is characterized by psychomotor retardation and, especially, altered behavior. The patient becomes disorderly, social graces and moral standards are impaired, and his conduct is frequently inappropriate. There is loss of initiative with no thought for the future. Self-consciousness is lost and he may be boastful, facetious, or jocular (*witzelsucht*). On the other hand, some patients are unusually irritable, distractible, and hostile. Affect is usually flattened, but either euphoria or depression may be prominent. Apathy is more common than hyperactivity. Orientation for time and place is often disturbed, and the patient cannot easily adjust to change. Attention and ability to learn are impaired. Perception and memory may be defective. There is associated defect in abstract thinking, and the patient has great difficulty in synthesizing and organizing his thoughts and activities. The resultant poor intellectual performance is not necessarily related to memory impairment, and the over-all I.Q. need not be subnormal.

Disease of the limbic system. This portion of the central nervous system includes the cingulate gyrus and particularly those portions of the temporal lobe containing the amygdala, the hippocampus, and the uncus. These areas are interconnected

by a continuous chain of neurones with the posterior orbital cortex of the frontal lobe, the septal region, the diencephalon, mammillary bodies, and thalamus. Lesions in the limbic system in lower animals are associated with change in behavior, either rage or tameness. The Klüver-Bucy syndrome occurs in monkeys after bilateral temporal lobectomy. These animals demonstrate apparent loss of memory, visual agnosia, oral tendencies, hypersexuality, and tameness. Bilateral temporal lobe lesions in humans may be associated with symptoms similar to the above, but considerably modified. More commonly, bilateral lobe lesions in man are associated with a Korsakoff-like syndrome. Irritative lesions of the temporal lobe may cause mental and emotional symptoms manifested by illusions or hallucinations; affective symptoms; disturbances of thought, memory, or awareness of self; or alterations of consciousness or behavior. These phenomena may occur with or without associated psychomotor seizures (see Section 10.4). Lesions in the septal area cause reduction in or absence of emotional expression, and it is inferred that this area is associated with feelings of pleasure.

Diencephalic disease. The diencephalon is composed of the ascending reticular formation of the brain stem, thalamus, hypothalamus, and adjacent structures. Lesions of the diencephalon, even more clearly than those of other structures, produce their effects by release of facilitating or inhibiting mechanisms necessary for "balanced" human behavior. Disease of this area is often associated with emotional lability or spontaneous laughing or crying. In lower animals, lesions of the anterior diencephalon are associated with sham rage (i.e., sympathetic motor activity of rage probably without appropriate change of affect). Extreme excitement, savageness, and increased feeding drive are also evoked with experimental lesions of the anterior diencephalon. In humans a mania-like syndrome may be seen with disease in this area. Lesions of the posterior diencephalon in animals are associated with unusual tameness, sometimes to the degree of severe apathy. In man, disease in this area is associated with hypersomnia and akinetic mutism (see Section 10.4). Conscious sensory perception is affected in disease of the ascending reticular formation that interrupts the sensory inflow to the cerebral cortex.

Parietal lobe disease. Parietal lobe lesions may be associated with agnostic, apraxic, or aphasic phenomena; and differentiation of patients with these signs from those demented may be extremely difficult or impossible. The following features help distinguish generalized cerebral disease causing dementia from focal disease resulting in aphasic, agnostic, or apraxic symptoms. The patients with dementia more often show inappropriate or antisocial behavior; drowsiness or evidence of impaired consciousness; urinary or fecal incontinence; emotional lability or irritability; disorientation in all spheres; impaired fund of information, particularly for recent events; inability to deal with new concepts; and bilateral signs such as grasp reflexes. On the other hand, the demented patient need not have apraxia or language impairment.

The clinical manifestations of lesions of the parietal lobe may be difficult to differentiate from hysteria, and it is more common for signs of a parietal lobe lesion to be erroneously considered hysterical than vice versa. Thus, the patient with a parietal lobe lesion may appear apathetic and indifferent. There may be variability of performance, especially at the hands of different examiners. Bizarre symptoms such as distortion of body image or other spatial disorders may initially suggest the diagnosis of hysteria.

Occipital lobe disease. Occipital lobe lesions may cause visual illusions and hallucinations. Metamorphopsia, or distortion of images, may be simple, e.g., the illusion of objects appearing to be larger than they really are (megalopsia); or may be complex, e.g., the illusion of objects taking on strange affective qualities. Visual hallucinations may occur within one visual field (either in a hemianopic field or the normal field), or they may be generalized. Suggestion may influence the type of formed hallucination, for example, the hallucination of seeing Santa Claus at Christmas time. The intellectual and emotional

background of the individual is an important factor in the type of hallucination experienced. Visual hallucinations are not limited to lesions of the occipital lobe but rarely occur with lesions of the frontal lobe or retina and, of course, are as common in disease of the temporal lobe as with lesions of the occipital lobe. (It was thought that formed hallucinations were of temporal lobe origin and unformed or crude hallucinations were of occipital lobe origin. This differentiation is certainly not reliable and cannot be used as a localizing sign.) Just as hallucinations may suggest psychosis, other occipital lobe phenomena may simulate hysteria. Thus, patients with cortical blindness are usually indifferent to their illness. Such patients often deny blindness and confabulate. Visual agnosias and contralaterally reduced fields of vision of organic origin may be interpreted as hysteria. Visual disorientation may be difficult to differentiate from disorientation of more diffuse organic disease.

11.3 CLINICAL NEUROLOGY AND NEUROPATHOLOGY

SEYMOUR SOLOMON, M.D.

Histopathology

Cells of the nervous system react in certain general patterns to many different types of injury or stress. Neuroglia or interstitial cells follow one pattern; neurones, those cells which conduct impulses, react in another.

Neuroglia. Astrocytes are the predominant interstitial cells of the central nervous system. Oligodendroglia have long been thought to be responsible for myelin formation, and recent electron microscopic studies confirm that conclusion. Microglia may also be considered interstitial cells although their function is phagocytosis. Only the nuclei of interstitial cells are seen with Nissl stains, e.g., thionin, or with hematoxylin and eosin stains; the remainder of the cells' structures must be impregnated with gold or silver for visualization.

Injuries to the nervous system may result in degeneration of the interstitial cells as manifested by swelling of the cell bodies, fragmentation of the cell processes, and shrinking with hyperpigmentation

(pyknosis) of the nuclei. If injury is less severe, reactive gliosis occurs; i.e., the glial cells (predominantly the astrocytes) proliferate to replace destroyed tissue. The astrocyte divides by amitosis, and, in the early phase of reactive gliosis, cell bodies are numerous. Eventually, a gliotic scar is formed by a dense network of astrocytic fibers. Phagocytosis occurs after brain injury; microglia proliferate, as in an inflammatory reaction, and move toward the affected area while changing their shape and increasing in size to globular structures devoid of cell process. After ingesting degenerated tissue, these fat-laden granule cells migrate to blood vessels and discharge their products into the perivascular spaces. Corpora amylacea (amyloid bodies) are round, often laminated, amorphous bodies that stain with hematoxylin and are the cellular debris found especially around old areas of degeneration. Demyelination is manifested by swelling of the myelin sheath, then fragmentation of the myelin into lipid globules. The axis cylinder within the sheath may remain relatively intact.

Neurones. Injury to the neurone alters the cell body and its axone (axis cylinder) with its myelin sheath. Changes within the cell body may affect the Nissl substance (masses within the cytoplasm staining blue with methylene blue), neurofibrils (delicate fibers seen by silver impregnation), and Golgi apparatus (granular material scattered through the cell seen with osmic acid or silver stains), as well as pigments within the cell. The Nissl substance undergoes fragmentation and dissolution (chromatolysis). The neurofibrils swell and disintegrate. (Alzheimer's neurofibrillary changes in senile and presenile psychoses refer to the fusion of neurofibrils and their formation into tangled masses). The Golgi apparatus is dissipated with disease. After injury to the cell body, the axis cylinder (seen with silver stains) will first swell and then fragment. The surrounding myelin sheath (seen best with hematoxylin and iron stains) will degenerate when loss of the axis cylinder occurs, but, as noted above, the reverse need not apply. Acute injury to the neurone is manifested by swelling of the cytoplasm; chromatolysis of the Nissl substance; swelling and disintegration of the neurofibrils; swelling, hyperpigmentation, and fragmentation of the nucleus; and detachment and fragmentation of cell processes. The loss of the staining properties of the cell eventually leaves a "ghost cell." Chronic injury to the nerve cell is characterized by shrinkage of the cytoplasm, coalescence of the Nissl substance, shrinkage and increased tortuosity of cell processes, shrinkage and pyknosis of the nucleus, and eventual destruction of the nucleus, with death of the cell. The degenerated nerve cell then undergoes phagocytosis, i.e., neuronophagia.

Pathology seen in functional psychoses. Doubt exists with regard to the specificity of pathological changes in patients who come to autopsy with the clinical diagnosis of schizophrenia or other "nonorganic" psychosis. Some believe that fatty neuronal disease is a characteristic feature of these psy-

FIGURE 1. Glioblastoma multiforme. The massive tumor extends through the corpus callosum from one frontal lobe to the other. (From Zimmerman, H. M., Netsky, M. G., and Davidoff, L. M. *Atlas of Tumors of the Nervous System*, p. 34. Lea and Febiger, Philadelphia, 1956.)

FIGURE 3. Astrocytoma. The cells, predominantly fibrillary astrocytes, form a loose meshwork. Hematoxylin and eosin, 185 X. (From Zimmerman, H. M., Netsky, M. G., and Davidoff, L. M. *Atlas of Tumors of the Nervous System*, p. 30. Lea and Febiger, Philadelphia, 1956.)

chromes. The persistence of damaged cells rather than their complete destruction is claimed to be one of the underlying mechanisms for the schizophrenic syndrome. The damaged neurons have been found predominantly in the cortex of the prefrontal lobe, anterior cingulate gyrus, striatum (especially globus pallidus), and the anterior and medial nuclei of the thalamus. Since schizophrenia may be a group of different syndromes, these pathological features may be present in some patients and not in others.

Neoplasms of the Brain

The classical clinical manifestations of brain tumor, i.e., headache and papilledema, can no longer be regarded as adequate criteria for diagnosis. These features often occur late in the course of the disease, if at all. The chief manifestation of brain tumor is the pro-

FIGURE 2. Glioblastoma multiforme. The cells vary in size and shape; several multinucleated giant cells are seen. The palisading of cells adjacent to an area of necrosis is noted on the left. Hematoxylin and eosin, 100 X. (From Blackwood, W., Dooley, T. C., and Sommersville, J. C. *Atlas of Neuropathology*, ed. 2, p. 177. Williams & Wilkins, Baltimore, 1954.)

FIGURE 4. Oligodendroglioma. The prominent nuclei are surrounded by unstained foamy cytoplasm. Masson's trichrome stain, 200 X. (From Blackwood, W., Dooley, T. C., and Sommersville, J. C. *Atlas of Neuropathology*, ed. 2, p. 187. Williams & Wilkins, Baltimore, 1954.)

gressive nature of the patient's neurological symptoms or signs, whether they be generalized or focal. Generalized symptoms may include an organic mental syndrome, personality changes, convulsive seizures, headache, lethargy, or other symptoms of increased intracranial pressure. An organic mental syndrome and personality changes are particularly prevalent in frontal brain tumors but may be seen with neoplasms in any area of the brain. Tumor must be a primary consideration when convulsions originate during adult life, for such seizures are due to a cerebral neoplasm.²⁰

hemiparesis, hemisensory impairment, or homonymous hemianopsia. A cerebellar tumor, on the other hand, will manifest progressive symptoms and signs of ataxia of the trunk or the extremities on the same side as the lesion.

Intracranial neoplasms will be discussed with regard to incidence, age of onset, sexual predominance (if significant), site of origin, clinical characteristics (if the site of origin is other than the cerebral hemisphere or cerebellum), degree of malignancy, clinical course (if different than that expected on the basis of degree of malignancy), probability of complete surgical excision, response to radiotherapy, and gross and microscopic appearance.

The following is an outline of the incidence of intracranial neoplasms, listed in order of decreasing frequency.

- A. Gliomas: 45% of all intracranial neoplasms
- B. Metastatic tumors: 15%
- C. Meningiomas: 15%
- D. Hypophysial tumors and tumors of embryonic rests: 10%
- E. Tumors of nerves (acoustic neuromas): 8%
- F. Vascular tumors: 2%

Gliomas. Most primary brain tumors arise from glial (interstitial) cells. Few tumors under this classification are of other neuroectodermal origin. In the following classification only the most common neoplasms are listed.

- A. Tumors of glial origin
 1. Glioblastoma multiforme
 2. Astrocytic
 - a) Astrocytoma
 - b) Astroblastoma
 - c) Spongioblastoma polare
 3. Oligodendroglioma
 4. Ependymal
 - a) Ependymoma
 - b) Papilloma of choroid plexus
 - c) Colloid cyst
- B. Tumors of the pineal gland
 1. Pinealoma
- C. Tumors of neuronal or retinal origin
 1. Medulloblastoma
 2. Retinoblastoma

Glioblastoma multiforme. This tumor accounts for 55 per cent of all gliomas. It is a tumor of adult life arising within a cerebral hemisphere. This neoplasm is the most malignant of all primary brain tumors and duration of life is rarely more than 1 year after onset. Response to radiotherapy or surgery is poor. The gross appearance (Figure 1), is that of a soft, hemorrhagic, necrotic, infiltrating mass which often spreads from one hemisphere to the other across the corpus callosum. Under the microscope (Figure 2), both the cells and their nuclei show great variation in size and shape with giant amoeboid cells and numerous mitoses. The cells may form a pseudopalisade pattern around areas of necrosis. Endothelial proliferation is evident; necrosis and hemorrhage are marked.

Tumors of astrocytic origin

Astrocytoma. This tumor makes up 20 per cent of all gliomas. In adults the tumor occurs within a cerebral hemisphere; in children it is found within the cerebellum. The tumor is benign, can be extensively excised, and responds moderately well to radiotherapy. It appears as a rubbery, infiltrating, poorly defined mass, with a tendency to pseudocyst formation. The latter is particularly true in the cerebellum where the tumor may present as a mural nodule in the pseudocyst. Microscopically, the tumor appears either as a mass of glial fibrillae (Figure 3), or as prominent large protoplasmic astrocytes. Sometimes degenerative changes in the astrocytes form amoeboid or gemistocyte cells. Vascular proliferation is noted from both endothelial and adventitial cells. Calcification is evident.

Astroblastoma. The astroblastoma is an uncommon tumor of early adult life occurring within a cerebral hemisphere. It grows more rapidly than an astrocytoma, cannot be completely excised, and responds only slightly to radiotherapy. It is firm, sometimes hemorrhagic, and may appear fairly well circumscribed. On microscopy the tumor is seen to have a loose texture with cells arranged around blood vessels in a pseudorosette formation. Long processes extending from the cell bodies to the blood vessel wall are seen with gold stains.

Spongioblastoma polare. This is a rare tumor, beginning in childhood or adolescence, with origin in the area of the third or fourth ventricle or midbrain. There may be early signs of increased intracranial pressure due to blockage of ventricles, as well as signs implicating the midbrain. Rate of growth is slow to moderate, but the course of disease may be relatively rapid due to the tumor's location. The site of origin precludes surgery, and response to radiotherapy is minimal. The tumor appears as a firm mass, only fairly well demarcated. Microscopic examination reveals spindle-shaped cells often arranged in parallel, irregular bands with elongated nuclei and long processes extending from one or both poles of the cells.

Oligodendroglioma. The oligodendroglioma accounts for 5 per cent of all gliomas and usually begins in adult life within a cerebral hemisphere. The tumor is benign, can be completely removed, and has slight to moderate response to radiotherapy. It appears as a solid, well demarcated mass, sometimes containing cysts, hemorrhages, and, usually, areas of calcification. The calcification can often be seen in roentgenograms of the skull. Microscopically (Figure 4), one sees densely packed cells in uniform distribution. The scanty cytoplasm of the cell forms a halo-like zone around the conspicuous dark nucleus. Calcium deposits are prominent.

Tumors of ependymal origin

Ependymoma. The ependymoma constitutes 6 per cent of glial tumors and is predominantly a tumor of childhood and adolescence but often occurs in adults as well. It arises from the lining of the ventricles, particularly the fourth ventricle. The tumor is benign but usually causes increased intracranial pressure due to blockage of the ventricular system, and its course may, therefore, be subacute. It can be only partially excised, but there is moderate response to radiotherapy. The tumor appears as an infiltrating mass. Under the microscope (Figure 5), there is a dense mass of cells with large oval nuclei. Many cells form perivascular rosettes or papillary tufts.

Papilloma of the choroid plexus. This type of tumor makes up approximately 2 per cent of glial tumors. It is predominantly a tumor of children, especially males. The tumor arises within the ventricles, most often the fourth ventricle, and causes increased intracranial pressure with hydrocephalus. The tumor is benign, can be completely removed by surgery, and responds moderately well to radiotherapy. It appears as a relatively small nodule within the ventricle. Microscopically, one sees columnar or cuboidal cells covering papillae with vascular cores.

Colloid cyst. The colloid cyst accounts for approximately

2 per cent of glial tumors and usually occurs in early adult life. It arises from the rostral portion of the roof of the third ventricle, is often mobile, and may cause intermittent increased intracranial pressure due to occlusion of the foramen of Munro. The tumor is benign and can be completely excised, but it does not respond to radiotherapy. It appears as a smooth cyst, and microscopically the cyst wall is lined by a single layer of columnar or cuboidal cells.

Pinealoma. This is a rare tumor of the pineal gland usually occurring during the first 2 decades of life almost always in males. By compressing the quadrigeminal plate, it causes paralysis of upward gaze (Paranaud's syndrome); compression of the underlying aqueduct of Sylvius results in symmetrical hydrocephalus. Precocious puberty, sometimes seen with this tumor, may be due to its compression of the hypothalamus rather than to secretion of an occult hormone. The tumor is histologically benign, but the course is affected by its vital location. It cannot be surgically removed but there is often excellent response to radiotherapy. The tumor appears as a smooth encapsulated mass although sometimes it is invasive. On microscopy one sees many lymphoid cells and clusters of large cells with prominent nuclei containing one or two nucleoli, all within a stroma of connective tissue.

Medulloblastoma. This tumor accounts for 6 per cent of all "glial" tumors (it is truly of neuronal rather than glial origin). It occurs in childhood, more frequently in boys than girls. The tumor usually arises in the midline of the cerebellum and causes increased intracranial pressure by expanding from the roof of the fourth ventricle and blocking cerebrospinal fluid outflow. The neoplasm is highly malignant, and cells may exfoliate and disseminate through the cerebrospinal fluid, becoming implanted in other parts of the cerebrospinal axis. It can be extensively excised, and there is usually an excellent histological response to radiotherapy. Unfortunately, recurrence is rapid, and the course is usually 6 to 9 months in duration. The tumor does not appear as a friable invasive mass. Under the microscope (Figure 6), it is very cellular with small pear-shaped cells containing prominent dark staining nuclei frequently in mitoses. Some cells may be grouped into pseudorosettes.

Metastatic tumors. These make up approximately 5 per cent of all intracranial neoplasms. The lesions usually occur in adults and arise from carcinoma of the lungs or breast, much less commonly from malignancies of kidneys and other organs. Death usually occurs within the 1st year, but often radiotherapy prolongs useful life. Metastases (Figure 7) appear as firm, well demarcated masses. Microscopically, the tumors often resemble the primary lesion, but sometimes they are markedly altered and anaplastic.

Meningiomas. Meningiomas account for 15 per cent of all intracranial tumors and usually occur in adults. These neoplasms arise from the meninges of the sagittal sinus, the sphenoid ridge, or over the convexity of the cerebrum, and less commonly from any other site covered by meninges. The clinical characteristics depend, of course, on the specific site of origin. Meningiomas often cause hyperostosis of the adjacent bone which may be seen or palpated on examination or visualized in roentgenograms of the skull. The tumor is benign and grows slowly, although, rarely, meningiomas may become malignant. If accessible, it can be completely removed, but response to radiotherapy is slight. The tumor appears as a firm, gritty, encapsulated mass, extending from the inner surface of the dura and compressing underlying tissue. Under the micro-

scope one or a combination of the following features may be seen. (1) Fibroblastic elongated cells form reticulin and collagen. (2) Meningothelial large cells with vesicular nuclei are sometimes arranged in whorls (Figure 8), the centers of which may be replaced by calcium to form psammoma bodies. (3) Mesenchymal bipolar or multipolar cells have long processes intertwined into a loose network. (4) Angioblastic, endothelial cells line vascular spaces.

Tumors of the pituitary. Tumors arising from the pituitary or from embryonic rests adjacent to the pituitary constitute approximately 10 per cent of intracranial neoplasms.

Chromophobe adenoma. The chromophobe adenoma is the most common tumor of this group. It occurs in adult life from non-endocrine-producing cells of the pituitary. The tumor's expansion from the pituitary fossa causes compression of the optic chiasm and resultant bitemporal hemianopsia. Compression of endocrine-secreting cells of the pituitary results in hypopituitarism. The tumor is benign, and response to radiotherapy is usually good to excellent. If radiotherapy fails, complete resection is possible. The tumor appears as a soft, circumscribed mass. Under the microscope alveolar clusters of cells are seen with poorly staining cytoplasm but deeply staining nuclei.

Eosinophilic adenoma. This tumor occurs much more commonly in adults than in children and results in acromegaly or gigantism, respectively. It is benign and responds very well to radiotherapy; surgery is rarely necessary. The tumor consists of a small circumscribed mass within the pituitary fossa. Microscopically, one sees groups of cells in alveolar patterns. The cytoplasm surrounding a vesicular nucleus is filled with eosinophilic granules.

Basophilic adenoma. A basophilic adenoma of the pituitary is a very rare tumor. Clinical manifestations of Cushing syndrome (see Section 10.4) are almost always due to hyperplasia of the adrenal cortex rather than to this tumor of the pituitary. The tumor is benign and appears as a small, sometimes microscopic, nodule made up of cells with basophilic granules in the cytoplasm.

Craniopharyngiomas. These tumors occur one half or one third as commonly as chromophobe adenomas and are somewhat more frequent in childhood and adolescence than during adult life. The tumors arise above the pituitary fossa and usually compress the optic chiasm, causing bitemporal hemianopsia. Symptoms of hypothalamic disease and hypopituitarism often occur. Calcification frequently present within the tumor may be seen in roentgenograms of the skull. The tumor is benign, and complete removal by surgery is rare, but some response to radiotherapy may occur. It appears as an irregular grapelike mass of encapsulated cysts that contain thick oil-like fluid. On microscopic examination (Figure 9), the cysts are lined by stratified squamous epithelium, forming papillary masses. Other forms of epithelial tissue may be seen. Calcification is frequently present.

Other tumors arising from embryonic rests in the midline at the base of the brain include teratomas, dermoid cysts, epidermoids, chordomas, and lipomas.

Tumors of cranial nerves

Acoustic neuroma or Schwannoma. Arising from the sheath of the acoustic nerve, the acoustic neuroma or Schwannoma is the most common tumor of nerves.

FIGURE 11. Cerebral infarction due to occlusion of the major inferior branches of the middle cerebral artery. The infarct is of 3 weeks duration and no longer swollen. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 17. Williams & Wilkins, Baltimore, 1964.)

FIGURE 10. Acoustic neuroma. Spindle-shaped fibroblasts are arranged in interlacing palisades. Hematoxylin and eosin, 185 X. (From Zimmerman, H. M., Netsky, M. G., and Davidoff, L. M. *Atlas of the Nervous System*, p. 66. Lea and Febiger, Philadelphia, 1956.)

FIGURE 9. Craniopharyngioma. A layer of columnar cells lines several cysts. Hematoxylin and eosin, 150 X. (From Zimmerman, H. M., Netsky, M. G., and Davidoff, L. M. *Atlas of the Nervous System*, p. 88. Lea and Febiger, Philadelphia, 1956.)

FIGURE 12. Cerebral infarction approximately 1 day old. Into the edematous and disintegrating brain tissue leukocytes have emigrated from dilated blood vessels. Hematoxylin and eosin, 220 X. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 19. Williams & Wilkins, Baltimore, 1964.)

FIGURE 13. Cerebellar infarction approximately 1 day old. Into the edematous and disintegrating brain tissue leukocytes have emigrated from dilated blood vessels. Hematoxylin and eosin, 220 X. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 38. Williams & Wilkins, Baltimore, 1964.)

FIGURE 15. Chronic (tuberculous) meningitis. A thick greyish-white plate is predominant over the base of the brain. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 53. Williams & Wilkins, Baltimore, 1964.)

FIGURE 16. Rabies. In a Purkinje cell of the cerebellum are rounded intracytoplasmic inclusions, Negri bodies (arrows). Hematoxylin and eosin, 1,000 X. (Courtesy of Dr. T. Poon and Dr. A. Hirano.)

This tumor accounts for 8 per cent of all intracranial tumors. It occurs in adults, females more often than males. The tumor is located in the cerebellopontine angle, and symptoms result from involvement of the acoustic nerve and compression of adjacent trigeminal and facial nerves and cerebellum. The tumor is benign and can often be completely excised, but it does not respond to radiotherapy. The neuroma appears as an irregular, encapsulated, firm mass surrounding the

acoustic nerve. Microscopically (Figure 10), elongated fibroblastic cells with dark nuclei are seen in palisading interlacing rows associated with a great deal of collagenous tissue.

Optic nerve glioma. The optic nerve glioma is a rare tumor of the 1st decade of life arising from glial elements of the optic nerve. There is associated blindness and sometimes exophthalmus. Although the tumor is histologically benign, it infiltrates the optic chiasm and adjacent tissue, eventually causing death. In the early stage, however, it can be completely excised, and

FIGURE 17. Encephalitis: in this case due to herpes simplex virus. Edematous brain tissue has compressed the ventricles. Hemorrhages and necrosis are evident in the temporal lobe. (Courtesy of Dr. H. M. Zimmerman.)

FIGURE 18. Kernicterus. Bile pigment is predominant in the deep nuclear structures, especially the subthalamic nucleus and Ammon's horn. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 97. Williams & Wilkins, Baltimore, 1964.)

FIGURE 19. Normal Ammon's horn, i.e., the portion of the hippocampus that projects into the temporal horn of the lateral ventricle. A layer of large pyramidal cells curves into the nerve cell layer of the dentate gyrus. Thionin. 9 \times . (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 25. Williams & Wilkins, Baltimore, 1964.)

there is good response to radiotherapy. The tumor appears as a bulblike swelling around the nerve. Under the microscope astrocytes and spongioblasts are the predominant cells.

Vascular tumors

Hemangioblastomas. Tumors of vascular origin are mainly hemangioblastomas. They account for only 1 or 2 per cent of all intracranial tumors and may be seen in adults as well as children, occurring more commonly in males than females. The most frequent site is the cerebellum. When this cerebellar tumor is associated with cystic disease of the kidneys, pancreas, or other organs and with angiomatosis of the retina, the clinical picture is called Hippel-Lindau disease. The benign tumor can be totally removed, and it also responds well to radiotherapy. It appears as a small red nodule within a cyst, and, on microscopy, small immature blood vessels or large endothelial cells are seen within a very prominent reticular network.

Vascular Diseases of the Central Nervous System

Vascular lesions are the major cause of organic brain disease, yet the number of different diseases under this classification is relatively small. The lesions and their associated signs may be focal or scattered. Abrupt onset is most characteristic of sudden occlusion or rupture of an artery. Vasospasm as a cause of transient cerebral ischemia is a controversial concept that has been falling into disrepute and should be rarely considered. Occult cardiovascular factors associated with cerebrovascular disease are probably the most common causes of transient cerebral phenomena. Atherosclerosis and associated thrombosis of major arteries, i.e., the carotid, vertebral, and basilar vessels or their main branches, are frequently associated with transient ischemic attacks although more often infarction with neurological deficit occurs. With atherosclerosis of many small cerebral vessels onset of generalized symptoms is insidious and progression is slow.

FIGURE 20. Ammon's horn affected by anoxia. There is loss of the pyramidal cell layer from A to C. That section between A and B (Sommer's sector) is particularly vulnerable to anoxia. Thionin. 10 \times . (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 25. Williams & Wilkins, Baltimore, 1964.)

Stenosis or occlusion of arteries

Atherosclerosis. Atherosclerosis is the most common vascular disease. On examination of the affected vessel one sees irregular yellow plaques projecting into the lumen with stenosis or occlusion often due to superimposed thrombosis. In the early stages, fat-containing cells are deposited in the intima of the vessel, and there is associated buildup of connective tissue. Later, degeneration with hyalinization and calcification occur.

Hematological causes of thrombosis (see below) include sickle cell anemia, thrombotic thrombocytopenia, and polycythemia vera. Arteritis is characterized by the infiltration of all arterial layers by mononuclear cells causing fibroblastic proliferation and subsequent stenosis or occlusion. These changes may be seen in syphilis and toxic encephalitis, or as the result of infected emboli. Temporal arteritis and collagen diseases (see below) cause similar vascular occlusions.

Cerebral infarction

Thrombotic infarction. Most cerebrovascular diseases are due to thrombotic infarction. Embolic infarction and cerebral hemorrhage are much less common. The symptoms and signs of cerebral artery thrombosis may occur briefly (transient ischemic attack) or suddenly (within minutes or hours), or, rarely, they may slowly progress. Progression for more than 48 hours requires primary consideration of cerebral neoplasm. Thrombotic infarctions usually occur within the arterial tree of an atherosclerotic carotid or middle cerebral artery, less commonly within the vertebrobasilar arterial system. Stenosis or occlusion of the internal carotid artery is a very common cause of cerebral infarction. The atherosclerotic lesion upon which thrombosis occurs is usually located just beyond the bifurcation of the common carotid artery.

FIGURE 21. A, a portion of normal cerebral cortex. Nissl stain. 52 \times . B, cerebral cortex affected by anoxia. The cortex has shrunken in depth. Loss of neurons accounts for the decreased quantity of cell bodies, especially in the third layer of the cortex. Nissl stain. 60 \times . (Courtesy of Dr. H. M. Zimmerman, Montefiore Hospital and Medical Center, New York, New York.)

The classical syndrome of internal carotid occlusion is that of blindness of the ipsilateral eye (supplied by the ophthalmic branch of the internal carotid artery) and contralateral hemiparesis, hemisensory impairment, and homonymous hemianopsia. Usually only fragments of the complete syndrome are seen. Occlusion of the main trunk of the middle cerebral artery causes the contralateral signs above. Occlusion of the anterior cerebral artery is associated with contralateral paresis of the lower extremity, and occlusion of the posterior cerebral artery results in contralateral homonymous hemianopsia. Sudden occlusion of the basilar artery is incompatible with life. More commonly, stenosis within the vertebral or basilar arteries causes ischemia or infarction of the brain stem with a variety of ipsilateral cranial nerve signs coupled with contralateral motor and/or sensory signs. The most common infarct of the brain stem is within the distribution of the posterior inferior cerebellar artery and is usually due to thrombosis of the adjoining vertebral artery. The resultant lateral medullary syndrome is characterized by vertigo and nystagmus with ipsilateral ataxia and facial analgesia, and by contralateral analgesia of the trunk and extremities. Ipsilateral Horner's syndrome and paresis of the soft palate, pharynx, and larynx are usually present; ipsilateral involvement of the sixth, seventh, or eighth cranial nerves sometimes occurs.

Embolic infarction. Embolic infarcts are sudden in onset and often multiple. Emboli usually arise from mural thrombi of the heart, disseminated during a bout of cardiac arrhythmia, or from valvular vegetations of subacute bacterial endocarditis. Fat emboli result from crushing injuries to the bone or other manipulation of fatty tissue; characteristically, a time lapse of 3 to 6 days occurs between the initial injury and the onset of cerebral symptoms. Air embolism may occur in excessively rapid decompression or during surgical operations that allow air into the arterial system, e.g., surgical abortion.

Treatment. The treatment of cerebral infarction is still unsatisfactory. Thromboendarterectomy of the carotid artery has not yet proven to yield better results than medical measures. It may be indicated in a young individual with a single arterial lesion that has caused ischemia but not major infarction. Anticoagulant therapy has been similarly disappointing but may be indicated in nonhypertensive individuals with transient ischemic attacks, especially within the distribution of the vertebrobasilar arteries, and it is indicated in aseptic embolic disease of cardiac origin. A potent cerebrovascular dilator is not yet available, but papaverine, carbonic anhydrase inhibitors (e.g., acetazolamide (Diamox)), and intermittent administration of 5 per cent CO_2 and oxygen may be beneficial. Hypothermia has not been of proven value. The administration of low molecular weight dextran to decrease sludging within vessels adjacent to the infarct has not met with success. Hyperbaric oxygen chambers have been used with benefit but are not yet practical.

Pathogenesis. The development of infarction is attributable to reduced blood supply to a local area. Complete arterial occlusion need not be present, for anoxia of varying duration and severity may cause

irreparable damage. The rate of reduction in blood flow is an important factor in the development of infarction, as slow reduction allows collateral circulation to develop within the ischemic zone and may prevent the damage that almost invariably occurs with sudden major occlusive disease. Neurones are much more susceptible to ischemic damage than astrocytes, and there is considerable difference in vulnerability of nerve cells. Neurones of the cerebral cortex, particularly Ammon's horn, and Purkinje cells of the cerebellar cortex are most vulnerable to ischemia (Figures 19 to 22). An infarct (Figures 11 and 12) appears as a pale, often wedge-shaped zone of softening, first swollen, then shrunken. Embolic infarcts are frequently multiple and more often hemorrhagic than infarcts of thrombotic origin. The microscopic reactions of neurones and glial cells to these and other injuries have been described above.

Cerebral hemorrhage. Petechial hemorrhages are seen as small, scattered lesions and may be associated with severe infections or toxic reactions. Larger cerebral hemorrhages are due to rupture of an artery, in patients with atherosclerosis and hypertension, or to rupture of an aneurysm. Much less common causes of hemorrhage include blood dyscrasias and vascular malformations. A large cerebral hemorrhage is manifested by the sudden onset of loss of consciousness and focal neurological signs; it is often catastrophic. Blood is usually found in the spinal fluid. Surgical evacuation of the hematoma may be indicated if it acts as an expanding mass.

Aneurysm. Ruptured aneurysms in or near the circle of Willis are the most common cause of subarachnoid hemorrhage. The hemorrhage is manifested by the sudden onset of headache and usually loss or alteration of consciousness; nuchal rigidity is found on examination. If blood from the ruptured aneurysm breaks into the parenchyma, focal neurological signs occur (Figure 23). Aneurysms may also cause signs by their pressure on adjacent structures, i.e., the oculomotor nerve.

Congenital aneurysms are due to defects in the media of the arterial wall, especially at the bifurcation of vessels. Mycotic aneurysms are secondary to infection often spread from subacute bacterial endocarditis. Atherosclerosis or trauma may weaken an arterial wall and cause an aneurysm. A carotid cavernous sinus fistula is due to rupture of the carotid artery within the cavernous sinus and causes pulsating exophthalmos, ophthalmophagia, and bruit. Dissecting aneurysm of the aorta may occlude or extend into the carotid artery.

Most neurosurgeons advocate ligation of the neck of the aneurysm, if accessible, or ligation of the common carotid artery supplying the aneurysm, but there is no statistical proof to indicate that surgical therapy produces better results than simple bedrest and supportive measures.

Other congenital vascular lesions

Arteriovenous malformation. An arteriovenous (A-V) malformation consists of a tangle of abnormal arteries and veins within the cerebrum. After aneurysms, this lesion is the most common intracranial vascular anomaly. Seizures may occur and a bruit is frequently heard, but most often the first clinical

manifestation is bleeding, with resulting neurological defect. The intracerebral or subarachnoid hemorrhage caused by an A-V malformation is usually less serious than the hemorrhage associated with a ruptured aneurysm.

Sturge-Weber's disease. This disease is manifested by a facial wine-colored nevus, contralateral neurological signs, epilepsy, and glaucoma. Roentgenograms of the skull reveal curvilinear calcifications that have developed in atrophic cortex underlying a large tortuous angiomatous malformation, most commonly over the occipital area. Angioma of the choroid of the eye is often present.

Familial telangiectasis. Familial telangiectasis (Rendu-Weber-Osler disease) is a condition manifested by multiple telangiectases of skin and mucous membranes. Similar involvement of the brain frequently results in small hemorrhages.

Ataxia telangiectasia. As the name implies, this condition adds cerebellar signs to congenital, often familial, oculocutaneous telangiectases. Recurrent sinopulmonary infections occur, and choreoathetosis and oculomotor apraxia may be associated features. Immunological deficiency is an underlying factor. Degenerative changes are found in the cerebellum and other areas of the central nervous system (CNS).

Venous occlusion. Primary aseptic thrombosis of dural sinuses is sometimes seen in children who suffer from malnutrition or who have serious systemic illness. Thromboses of dural sinuses are more commonly secondary to pyogenic infections (see below). These lesions are manifested by increased intracranial pressure and congestion in the area of the head or face normally drained by the affected sinus and its contributory veins. Venous thrombosis, especially of cortical veins, may be a postpartum complication; convulsive seizures and focal signs are due to congested cerebral tissue.

The collagen diseases. This is a group of diseases affecting predominantly connective tissue. Degeneration of connective tissue is associated with inflammatory cell infiltration and fibroblastic proliferation. These illnesses are discussed under diseases of the vascular system because most CNS symptoms and signs of collagen diseases are due to multiple small vessel occlusions. The resultant zones of ischemia gradually coalesce to form infarctions. All organ systems may be affected, and virtually any symptom or sign referable to the central or peripheral nervous systems may occur.

In systemic lupus erythematosus, central nervous involvement may occur early in the course. Convulsive seizures and "toxic" psychosis are common.

Peripheral neuropathy develops in 30 to 50 per cent of patients with polyarteritis nodosa, but central nervous system involvement is much less common.

Giant cell arteritis (temporal arteritis) occurs in patients over the age of 55 and is manifested by headache in the area of swollen, hard, and tender temporal arteries of the scalp. The disease often involves other arteries, and inflammation of the retinal arteries results in blindness of one or both eyes in approximately 25 per cent of patients.

Arteritis of the aorta and its major branches (pulseless disease or Takayasu's disease) is most common in young women, and neurological symptoms are due to ischemia of the brain stem or cerebrum.

Thrombotic thrombocytopenic purpura, not uncommonly causes multiple infarcts or hemorrhages in the cerebrum as well as in other organs. Other collagen diseases include derma-

FIGURE 22. A, a section of normal adult cerebellar cortex. Note the layer of Purkinje cells between the outer molecular layer and the inner granular layer of cells. Nissl stain. 68 \times . B, cerebellar cortex affected by anoxia. Loss of Purkinje cells leaves empty spaces in their place. Nissl stain. 55 \times . (Courtesy of Dr. H. M. Zimmerman.)

tomyositis, scleroderma, and rheumatoid arthritis, but these diseases do not usually affect the central nervous system. Rheumatic fever is considered by some to be a collagen disease (see Sydenham's chorea, below). Most collagen diseases respond to steroid therapy.

Disease of the hematopoietic system

Sickle cell anemia is a hereditary disease of Negroes. The neurological features are due to cerebral thrombosis or hemorrhage. Roentgenograms of the skull reveal a ground glass appearance of the bone with spicules projecting through the outer table.

Hemophilia is a hereditary disease of abnormal blood coagulation affecting males but transmitted by the female. The neurological complications are associated with intracranial bleeding.

Polycythemia vera is characterized by an excess of red blood cells as well as other cellular elements of the blood with associated increased blood viscosity. It usually begins after the age of 50 and affects men more often than women. Headaches and other nonspecific neurological symptoms are common. More serious features are associated with thrombosis of cerebral vessels, either arteries or veins. Venous congestion may cause increased intracranial pressure. Cerebellar hemangioblastoma is sometimes associated with this disease.

Macroglobulinemia, Waldenström's disease, is considered a neoplasia of the reticuloendothelial system and usually occurs in middle or late adult life, affecting males more commonly than females. Its course is relatively chronic. Hemorrhagic diatheses occur in two thirds of these patients. Cerebral involvement may be acute and focal due to hemorrhage, or multifocal or diffuse due to lymphocyte and plasma cell infiltration. Peripheral nerve lesions may also occur.

Leukemia often causes cerebral disease because of hemorrhage or leukemic infiltration. Other lymphomas, Hodgkin's disease, lymphosarcoma, and reticulosarcoma involve the central nervous system approximately 25 per cent of the time. Progressive multifocal leukoencephalopathy (see below) may be associated with leukemia or lymphoma.

Subacute combined system disease of pernicious anemia, thrombocytopenic purpura, and kernicterus (see below) may also be considered under diseases of the hematopoietic system.

Trauma to the Central Nervous System

In most cases these diseases can be diagnosed on the basis of history, but unrecognized trauma may be associated with convulsive seizures, alcoholic intoxication, or other illnesses. Neurological signs of cerebral trauma may be focal or diffuse and, with the exception of dural hemorrhages, usually show evidence of gradual improvement. Recovery is not always complete, and focal signs as well as mental and personality changes may be permanent sequelae. Post-traumatic epilepsy and other neurological lesions occur more commonly after open head injuries than after closed head injuries (see Section 10.4).

Degrees of cerebral trauma

Cerebral concussion. This is a clinical term denoting unconsciousness with rapid recovery and lack of residual cerebral signs. Repeated cerebral concussions, on the other hand, may eventually lead to irreversible brain damage, as seen, for example, in the "punch drunk" boxer. Those few cases that have come to autopsy, as well as experimental studies, have revealed petechial hemorrhages and associated edema.

Cerebral contusion. In a patient with cerebral contusion, residual signs of cerebral injury are noted after recovery of consciousness but these signs usually show extensive improvement or complete clearing. The inferior aspects of the frontal (Figure 24) and temporal lobes are particularly subject to contusion. The injured areas of the brain appear discolored because of confluence of small hemorrhages and associated maceration of the parenchyma.

Cerebral laceration. The patient with cerebral laceration has severe and often permanent signs of cerebral damage after prolonged unconsciousness. The

FIGURE 23. A ruptured aneurysm and associated massive cerebral hemorrhage. (Courtesy of Dr. H. M. Zimmerman.)

lesion is often associated with a depressed skull fracture, and bony fragments may cause gross tears of the brain tissue.

Intracerebral hemorrhage, usually superficial, is frequently associated with severe head injury, i.e., contusion or laceration of the brain. The symptoms may simulate that of a subdural hematoma, and surgical therapy may be warranted.

Cerebral injury need not underlie the site of trauma, but may be *contrecoup*, i.e., opposite the point of trauma, due to shift of the brain against the confines of the skull. This occurs particularly when trauma is directed to the frontal or occipital portions of the head.

Postconcussion syndrome. The syndrome includes many symptoms, most often headache, dizziness, fatigue, irritability, and other personality changes. It is most difficult to evaluate because there usually are no accompanying objective neurological signs. This syndrome is in the "no man's land" between occult neuropathophysiological mechanisms and "pure" emotional phenomena.

Birth trauma. Trauma at the time of birth may result in cerebral palsy (see below). Cerebral edema associated with the birth process sometimes causes herniation of the uncus of the temporal lobe through the tentorium of the cerebellum. The subsequent ischemia of this portion of the temporal lobe may result in a small glial scar that later becomes epileptogenic and produces psychomotor (temporal lobe) seizures.

Dural hemorrhages. Dural hemorrhages may be cured by prompt diagnosis (verifying the clinical suspicion by angiography) and surgical evacuation.

Epidural hemorrhage. An epidural hemorrhage is usually acute because of arterial bleeding, most commonly from rupture of the middle meningeal artery in its course through a fractured temporal bone. After an initial loss of consciousness caused by trauma, the patient awakens for a short time. He then lapses into stupor and coma.

Subdural hematoma. A subdural hematoma is usually subacute or chronic (Figure 25) and due to bleeding from sheared veins in the subdural space as a result of trauma. It must be emphasized that a history of trauma need not be present and, particularly in infants or the elderly, this diagnosis must be suspected when a deteriorating neurological course is evident. Headache and other generalized symptoms of increased intracranial pressure are common. Focal signs need not be present or may be falsely localizing (e.g., shift of the cerebral peduncle against the tentorium of the cerebellum may cause hemiparesis ipsilateral to the intracranial mass). Subdural hematomas are located predominantly over the frontal and parietal areas of the brain. In the early stages, liquid blood or black clot is present, but soon organization occurs. New capillaries and fibroblasts grow from the dura and enclose the hematoma with a false membrane that grows increasingly dense. The new vessels within this membrane may exude serum or may rupture and cause additional bleeding, thus enlarging the total size of

the mass. When fully encapsulated, the hematoma appears as brown fluid; eventually the fluid turns yellow though still containing blood elements.

Subarachnoid hemorrhage and arteriovenous fistulas may result from trauma. Their manifestations have been noted above.

Other forms of trauma

Electric shock. Electric shock occurs by accidental contact with lines of moderate voltage and high amperage. Coma and almost any variety of central and peripheral nervous system signs may be noted. Electric convulsive therapy rarely causes permanent organic mental disease and very rarely death (see Section 10.1). The brain reveals small hemorrhages, perivascular edema, and zones of necrosis, as well as scattered neuronal degeneration.

Heat. Heat exhaustion is related to loss of water and chlorides. It is manifested by generalized weakness, headache, muscular cramps, nausea and vomiting; sometimes, loss of consciousness occurs. Heat stroke is a serious disease with a high mortality rate. Weakness, dizziness, stupor, sometimes delirium or convulsions, and eventually coma occur. High fever is associated with cessation of sweating. The fever must be quickly reduced to save the patient's life. Both the brain and meninges are edematous, petechial hemorrhages are present, and degeneration of nerve cells is seen.

Cold. Severe cold may be associated with peripheral neuritis, but disease of the brain does not occur. On the contrary, hypothermia lowers cerebral metabolism and oxygen consumption, facts which may be therapeutically applicable.

Radiation. Neurological symptoms and signs referable to an area of former radiotherapy are most often correctly attributed to recurrent malignancy. Occasionally, however, the clinical features are caused by radiation injury. The effects of such injury begin approximately 1 year after radiation and are progressive. The necrosis and demyelination of the central nervous system caused by radiation are associated with neuronal loss, destruction of oligodendroglia, and fibrous thickening, with resultant occlusion, of small blood vessels.

Burns. Burns may cause lethargy, disorientation, and seizures, as well as a variety of other mental and focal neurological signs. These phenomena appear to be due to alteration of cerebral blood flow, but toxic factors probably also play a large role. Cerebral edema and petechial hemorrhages are the chief pathological features.

Degenerative Diseases of the Central Nervous System (Including Deficiency States)

The degenerative diseases of the central nervous system still form a large "wastebasket" for illnesses of unknown etiology. One by one the pathophysiological mechanisms of these diseases are being understood. Thus, subacute combined degeneration is now known to be related to vitamin B₁₂ deficiency, and hepatolenticular degeneration has been found to be associated with defective copper metabolism. In many diseases a definite hereditary pattern has been discerned. Autoimmune reactions are currently thought to be an important mechanism in multiple sclerosis, but this and other demyelinating diseases have been particularly baffling. Metabolic and toxic etiologies probably will be found for many so-called degenerative diseases. Occult infectious processes with a mechanism akin to that of postencephalitic parkinsonism may be the underlying basis of some illnesses. The degenerative diseases remain the most frustrating in the search for an under-

lying cause and the most futile to treat. These diseases usually begin insidiously and progress slowly, but there is tremendous variability in their course.

Diffuse demyelinating diseases. In this group of diseases, the lesions may occur in small scattered plaques or may involve large areas. In any one case, all stages in the process of demyelination may be seen, from early breakdown of myelin sheaths and removal of debris by fat-laden phagocytic microglia (Figure 13), to glial proliferation and resultant scar. Sometimes further degeneration causes cavity formation within the glial scar. The degeneration of axis cylinders is usually dependent upon the severity of demyelination.

Multiple sclerosis. This is the most common demyelinating disease. The illness occurs between the ages of 20 and 40 years. Neurological signs may be referable to any part of the central nervous system. The most common features of multiple sclerosis are unilateral blindness due to retrobulbar neuritis; nystagmus and diplopia secondary to isolated paresis of extraocular muscles associated with brain stem lesions; hemiparesis of pyramidal tract origin; cerebellar

FIGURE 25. Chronic subdural hematoma. The mass displaces the brain toward the opposite side. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 167. Williams & Wilkins, Baltimore, 1964.)

FIGURE 24. Severe contusion of the frontal poles has resulted in their atrophy and distortion. (Courtesy of Dr. H. M. Zimmerman.)

FIGURE 26. Multiple sclerosis. The arrows indicate "plaques" of demyelination. Note their predominance in the ventricular area and near the cortex. X indicates the section of a deep gyrus, not an abnormal plaque. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 81. Williams & Wilkins, Baltimore, 1964.)

(intention) ataxia and scanning (staccato) speech; and spastic paraparesis with loss of sexual potency and impaired sphincter control due to spinal cord lesions. The symptoms often outnumber signs and, at the onset, the disease may be mistaken for neurosis. Euphoria, often present in these patients, may be also misinterpreted as *la belle indifférence* of hysteria. The course is characterized by exacerbations and remissions of unpredictable severity, duration, and frequency. The only laboratory aid in the diagnosis is an elevated γ -globulin content of the spinal fluid found in about 65 per cent of cases. Gross examination of the brain (Figure 26) reveals scattered grey, sharply demarcated plaques of demyelination variable in size and shape, most numerous in the areas of the ventricles. In recent areas of demyelination, microscopic examination shows destruction of myelin, swollen axis cylinders, and many fat-laden phagocytic cells. Old areas of demyelination (Figure 27) reveal complete myelin loss with fragmentation of axis cylinders and the formation of a dense glial scar. Often there is remarkable preservation of nerve cells within the demyelinated plaques.

Neuromyelitis optica (Devic's disease). This disease is probably a variant of multiple sclerosis in which lesions are fortuitously limited to the spinal cord and optic nerves.

Schilder's disease. This is a demyelinating disease with usual onset between the ages of 1 and 3 years, but it may begin in older children, adolescents, or young adults. The illness is characterized by bilateral cerebral signs; cortical blindness is one of the most common findings. The course is steadily progressive but may be either acute or chronic. On gross examination, bilaterally symmetrical destruction of the white matter is seen, usually beginning in the occipital lobes. Under the microscope, the demyelination characteristically terminates a few millimeters below the cerebral cortex, sparing the arcuate, "U," fibers that bridge the cerebral sulci.

Other diffuse demyelinating diseases

Encephalitis periaxialis concentrica (Balo's disease). This is a rare condition that may occur at any age and causes death after 1 to 2 years. Both focal and generalized signs of cerebral disease occur. It is distinguished by the concentric rings of demyelination of the cerebral white matter.

Subcortical encephalopathy (Binswanger's disease). This is another rare illness that ends in death after 1 or 2 years. It begins in late adult life and is characterized by progressive focal signs as well as dementia and seizures. Patchy demyelination is seen that spares the grey matter and may be due to atherosclerosis of small deep cerebral vessels.

Acute encephalopathies. Acute encephalopathies associated with exanthemata or vaccinations (see below) may be demyelinating rather than inflammatory diseases.

Leukodystrophies. Leukodystrophies (see below) are a group of diseases characterized by progressive demyelination, usually of a familial character, with onset in infancy.

Degenerative diseases affecting predominantly the cerebral cortex

Senile dementia. Senile dementia is manifested by chronic progressive mental deterioration (see Section 10.4) beginning after the age of 60 or 65 years. Focal neurological signs may occur but not gross defects. (In

FIGURE 27. Multiple sclerosis. Irregular, seemingly punched out zones of demyelination are evident in this section through the level of the fourth ventricle. Myelin stain. 2.6 \times . (Courtesy of Dr. H. M. Zimmerman.)

any case of progressive dementia, brain tumor in the frontal lobe, or other "silent" area, must always be considered.) There is not very good correlation between the severity of the pathological findings and the degree of clinical involvement. On gross inspection, the meninges may be thickened and opaque. The underlying brain, particularly the frontal lobes, exhibits generalized or scattered atrophy manifested by narrow convolutions and wide sulci. Ventricular enlargement is seen in the cut section, and small cavities within the parenchyma may be noted. Microscopic examination reveals Alzheimer's neurofibrillary changes (see above). Other neuronal degeneration leaves ghost cells and alters the lamination of the cortex. Senile plaques, characterized by large extracellular silver-staining masses with radiating fibrils, are prominent in the cerebral cortex and the basal ganglia, maximal in the areas of major cell damage. Corpora amylacea (see above) are found predominantly in the white matter, particularly under the ependyma and near old cavities.

Alzheimer's disease. This disease is classified as a presenile dementia, but there is considerable doubt as to the clinical and pathological distinction between Alzheimer's disease and senile dementia. The chief clinical difference is the younger age of onset. The main pathological difference is the greater prominence of senile plaques, neuronal degeneration, and neurofibrillary changes in Alzheimer's disease (Figure 28).

Pick's disease. Pick's disease is another form of presenile dementia, i.e., beginning before the age of 60. It is clinically similar to Alzheimer's disease but occurs more commonly in females than males. On inspection of the brain (Figure 29), there is marked localized, asymmetrical atrophy of all or part of the frontal lobe, temporal lobe, or, less commonly, parietal lobe. Under the microscope, severe neuronal loss is seen with destruction of normal cortical layers. Characteristic, but not invariable, are Pick cells, i.e., neurones with large argentophilic inclusions in the cytoplasm that may displace the nucleus. Severe demyelination and glial proliferation are associated microscopic features.

Degenerative diseases affecting predominantly the cerebral cortex and the basal ganglia

Huntington's chorea. This disease begins between 30 and 50 years of age, when dementia and chorea appear, although not always concurrently. The disease is inherited as a simple dominant, thus affecting half of every generation. A progressive course lasts approximately 15 years. On gross inspection of the brain there is atrophy of the basal ganglia and sometimes of the brain as a whole. Under the microscope, neuronal loss affects predominantly the small cells of the caudate and putamen nuclei, as well as the cerebral cortex, especially the frontal lobe. Associated glial proliferation is evident.

FIGURE 28. Alzheimer's presenile dementia. Senile argyrophilic plaques (SP) and Alzheimer's neurofibrillary degenerations (arrows) are seen in this section of the cerebral cortex. Modification of Bielschowsky's silver stain. 250 X. (Courtesy of Dr. H. M. Zimmerman.)

FIGURE 29. Pick's lobar atrophy. There is prominent shrinkage of the temporal lobe with generalized atrophy of the middle and anterior aspects of the hemisphere. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 113. Williams & Wilkins, Baltimore, 1964.)

Wilson's disease or hepatolenticular degeneration. This is a familial disease of adolescence and more often has a chronic rather than an acute course. It is characterized by dementia and a combination of cerebellar and parkinsonian signs. Kayser-Fleischer rings (grey-brown-green in color) are noted along the outer zone of the corneas. Portal cirrhosis of the liver is invariably present. In this disease of defective copper metabolism excessive copper deposits in tissues cause the clinical and pathological features. The findings of high copper output in the urine, along with amino aciduria, and low ceruloplasmin (the copper-carrying plasma protein) confirm the clinical diagnosis. Although the basic metabolic defect is unaffected, treatments with dimercaprol (BAL) to hasten copper excretion and penicillamine to decrease copper absorption are beneficial in prolonging life beyond the average 5 to 10 years. On gross inspection of the brain, there is wasting of the lenticular nuclei, especially the putamen, as well as other basal ganglia. Under the microscope, neuronal loss is predominant in the putamen, other basal ganglia, the frontal cortex, and the dentate nucleus of the cerebellum. Large phagocytic cells containing hemosiderin (Opalski cells) are characteristic of Wilson's disease. Proliferation of astrocytes with large nuclei and demyelination of the subcortical white matter are usually seen.

Jacob Creutzfeldt's disease. This is a rare illness that begins between the ages of 40 and 50 years. It is manifested by dementia and motor signs of pyramidal, extrapyramidal, and lower motor neurone disease causing spasticity, tremors, and atrophy, respectively. Death occurs within 3 months to 3 years. Pathologically the disease is characterized by diffuse degeneration of neurones in the cortex, basal ganglia, and other nuclear groups of the central nervous system, including the anterior horn cells of the spinal cord.

Parkinson-dementia complex. This is a peculiar disease characterized by a combination of senile dementia and parkinsonism found in 7 per cent of the native population of Guam. Most of the pathological features of parkinsonism (see below) and senile dementia are found, but argyrophilic plaques and Lewy bodies are usually absent.

Degenerative diseases affecting predominantly the basal ganglia

Parkinsonism. In the past, parkinsonism followed encephalitis much more often than it does at the present time. Most recent cases beginning in adult life are idiopathic. (It is no longer thought that arteriosclerosis plays a primary role in parkinsonism.) In addition, the syndrome of parkinsonism may be a manifestation of phenothiazine, CO, or Mn toxicity. Parkinsonism has a slow course and is characterized by rigidity, resting tremor, and slowness of movement. These features may occur together or separately. Akathisia rarely occurs. Oculogyric crisis, i.e., fixation of the eyes in one position for minutes or hours, is a manifestation of post-encephalitic parkinsonism. The symptoms of parkinsonism, particularly tremor, are intimately associated with the patient's emotional state, as evidenced by their increase with minimal psychological stress. The therapeutic administration of atropine-like compounds benefits rigidity more than tremor. Exercise is at least as important as medication in diminishing rigidity and maintaining mobility. Mobility may also be augmented by amphetamines. Surgical methods of destroying the lateral thalamus or globus pallidus often eliminate the contralateral tremor or rigidity, respectively. (Such surgery may also benefit other dys-

kinesias.) Loss of pigment and atrophy of the substantia nigra is seen on gross examination of the brain (Figure 30) as well as under the microscope. Neuronal disease with hyalin intracytoplasmic inclusions (Lewy bodies) and associated gliosis are most prominent in the substantia nigra. There is lesser involvement of the globus pallidus, other basal ganglia, and the cerebral cortex.

Dystonia musculorum deformans. This condition begins before or soon after puberty, is predominant in Jews, and is sometimes familial. The course is usually slowly progressive, but in some cases deterioration stops or remissions occur. The disease is characterized by slow writhing movements of the trunk, shoulders, and pelvic girdle. The few pathological studies of this condition have revealed neuronal loss in the caudate and putamen nuclei and sometimes in the pons and dentate nucleus of the cerebellum as well. Torticollis may be a *forme fruste* of dystonia musculorum deformans.

Senile chorea. Senile chorea is a slowly developing dyskinesia unassociated with dementia or other neurological signs. Grimacing and athetoid tongue movements are often prominent.

Other dyskinesias have been discussed elsewhere and are summarized in the section on examination (see Section 10.1).

Degenerative diseases affecting the cerebello-spinal system. Heredodegenerative spinocerebellar ataxias are the predominant group under this classification. These slowly progressive diseases form a spectrum with maximum involvement ranging from the cerebellum to the spinal cord or the peripheral nerves. In addition to disease of these sites, defects may include optic atrophy or retinitis pigmentosa; atrophy of cerebral cortex; degeneration of the red nucleus, the cochlear nucleus, or other brain stem nuclei. Thus signs of blindness, seizures, dementia, deafness, and pupillary and extraocular muscle palsies may accompany heredodegenerative spinocerebellar diseases.

Diseases predominantly cerebellar

Cerebellar degeneration or cerebello-olivary degeneration of Holmes. This condition is often familial and usually occurs in males in their 6th or 7th decade. The disease is manifested by cerebellar ataxia and dysarthria. There is gross atrophy of the cerebellum. Under the microscope, loss of Purkinje cells with preservation of basket cells is noted. Some reduction of the granular cell layer of the cerebellar cortex is also seen.

Olivopontocerebellar atrophy of Menzel. This disease is often familial and begins in the 2nd and 3rd decades. It is characterized by cerebellar ataxia, and parkinsonian features may occur later in the course. The pathological manifestations are neuronal degeneration of the olives and dentate nuclei, with lesser involvement of the Purkinje cells of the cerebellar cortex. Demyelination of fibers interconnecting the olives, pons, and the cerebellum causes gross atrophy of these parts. Involvement of the spinal cord is not uncommon.

Diseases predominantly spinal

Friedreich's ataxia. This is a familial disease of late childhood. Its clinical manifestations are ataxia of all extremities associated with position sense loss, areflexia, and bilateral Ba-

binski signs. There is microscopic evidence of degeneration of the dorsal nuclei of the spinal cord with demyelination of the posterior and lateral columns, the latter affecting both spinocerebellar and pyramidal tracts. Some involvement of the posterior nerve roots is also evident. Cerebellar cortical degeneration often occurs, and there are many other variations of this disease.

Hereditary spastic paraplegia. This condition is characterized by spastic weakness, then paralysis, affecting predominantly the lower extremities. Microscopic study reveals demyelination in the lateral columns of the spinal cord.

Amyotrophic lateral sclerosis. This is the only disease in this group not commonly hereditary, except among the natives of Guam and the other Mariana Islands where the disease is strikingly familial and occurs in 10 per cent of the population. The illness begins in middle or late life and, in contrast to the chronic courses of other diseases discussed above, amyotrophic lateral sclerosis ends in death after 2 to 4 years. Spastic and/or flaccid progressive weakness with atrophy and fasciculations, affect the extremities and bulbar musculature. Under the microscope, degeneration of the anterior horn cells is evident, as well as the motor cells of the medulla and the Betz cells in the cerebral motor cortex. Demyelination of the pyramidal tracts is a concomitant feature. Less acute variants of this disease are progressive spinal muscle atrophy with major involvement of the anterior horn cells, and primary lateral sclerosis with maximum involvement of the pyramidal tracts.

Disease predominantly of the peripheral nerves

Charcot-Marie-Tooth disease or peroneal muscular atrophy. This is a hereditary, slowly progressive disease beginning in the first 3 decades of life. It is manifested by weakness and atrophy of the lower legs and lower third of the thighs with distal sensory impairment. Similar, but less marked features affect the upper extremities. The pathological characteristics are myelin and axonal degeneration of the peripheral nerves. Neuronal degeneration in the spinal cord is either secondary to the peripheral nerve disease or, some believe, a primary defect. Charcot-Marie-Tooth disease is often associated with Friedreich's ataxia, just as Friedreich's ataxia may blend into the cerebellar degenerations.

Diseases associated with nutritional factors

Vitamin deficiency. Vitamins, especially of the B complex group, are essential for nerve metabolism.

B complex. Thiamine deficiency may result in beriberi and causes peripheral neuropathy. CNS disease is rare, but, in severe forms, mental symptoms and cerebral edema have been noted. Thiamine deficiency is a major factor in the cause of Wernicke's syndrome (see below).

Niacin deficiency (pellagra) often manifests symptoms of toxic psychosis, dementia, or convulsive seizures early in its course. Motor signs implicating the peripheral nerves, pyramidal tracts, cerebellum, or extrapyramidal system occur later, if at all. Pellagra is associated with neuronal loss of the cortex, as well as other areas of the CNS. In addition, there may be posterior and lateral column demyelination of the spinal cord.

Pyridoxine deficiency may cause convulsions in infants, but its pathological characteristics in adults are obscure.

Vitamin B₁₂ deficiency causes pernicious anemia. It is a disease of middle or late adult life. The neurological syndrome of subacute combined degeneration may develop within a few weeks or months, sometimes before clinical evidence of the hematological disorder. Achlorhydria is always present, and the Schilling test is diagnostic. The neurological signs implicating the spinal cord are spastic weakness and/or ataxia due to de-

FIGURE 30. Parkinsonism. The substantia nigra is well pigmented in the normal section of the midbrain (*left*). Neuronal loss in the substantia nigra is manifested by depigmentation of this area in the section (*right*) from a patient with parkinsonism. (Courtesy of Dr. H. M. Zimmerman.)

myelination of the lateral and posterior columns of the cord. Peripheral neuropathy is common. Cerebral involvement is manifested by neurotic symptoms or dementia and is associated with neuronal degeneration, perivascular demyelination, and petechial hemorrhages.

Vitamin A. Vitamin A deficiency in infants may cause mental retardation and hydrocephalus with papilledema.

Vitamin C. Vitamin C deficiency (scurvy), when severe, is sometimes associated with intracranial bleeding.

Vitamin D. Vitamin D deficiency (rickets), may result in tetany or convulsions late in its course.

Alcoholism. Nutritional deficiencies are often associated with alcoholism, which causes a variety of encephalopathies through a combination of vitamin deficiencies, especially of the B complex group, and other nutritional defects. The toxic effects of alcohol are the least important factor in Wernicke's and Korsakoff's syndromes.

Wernicke's syndrome. This condition is characterized by oculomotor palsies, pupillary alterations, and nystagmus with ataxia and tremor. An organic mental syndrome or toxic psychosis is usually an associated factor. Consciousness may be depressed, and convulsions sometimes occur. Thiamine deficiency is the predominant cause, and prompt intravenous administration of this vitamin may be life-saving. On microscopic examination, petechial hemorrhages are found in the midbrain and diencephalon, with neuronal loss in these areas as well as in the cerebral cortex.

Korsakoff's syndrome. This syndrome is manifested by confusion, disorientation, and amnesia (especially retrograde) with confabulation. Delirium tremens frequently precedes the psychosis. Polyneuropathy usually is present, and Wernicke's syndrome is often superimposed. Treatment with thiamine and glucose is less beneficial than in Wernicke's syndrome. Both neuronal disease and demyelination are found in the

brain, but the pathogenesis of this disorder is uncertain.

In other diseases associated with alcoholism, toxic factors appear to predominate over nutritional deficiencies. These diseases, acute and chronic alcoholic intoxication, delirium tremens, and primary degeneration of the corpus callosum, are considered toxic encephalopathies (see below).

Central pontine myelinolysis. This disease occurs primarily in adults and is characterized by rapidly progressive flaccid areflexic quadriparesis. In addition, there may be progressive weakness of the facial and tongue musculature as well as emotional lability and other pseudobulbar phenomena. Death occurs within weeks. Most often a history of chronic alcoholism is noted, but other causes of nutritional deprivation are also associated with this disease. Pathological examination reveals a focus of demyelination in the center of the basilar portion of the middle and upper pons with preservation of nerve cells, axis cylinders, and vascular structures.

Protein deficiency. Seen commonly in areas of chronic famine, protein deficiency causes a complex disease of young children called Kwashiorkor. It is manifested by mental retardation and behavioral disturbances, retarded growth with muscle wasting, and sometimes tremors. The skin is pigmented and cracked; diarrhea and edema are common. If an adequate diet is not administered, death occurs. The neuropathological features are minimal, but cerebral edema and congestion are often noted.

Degenerative diseases associated with systemic malignancy

Progressive multifocal leukoencephalopathy. This disease usually occurs in late adult life and causes death within 2 to 6 months. It is characterized by lethargy, progressive dementia, and multifocal signs of central nervous system disease. This illness is usually associated with a malignant lymphoma which, it is postulated, impairs immunological mechanisms enough to allow virus infiltration. Under the microscope, one sees perivascular demyelination disseminated throughout the cerebrum, multiple small zones becoming confluent. Monster-sized astrocytes and oligodendroglia with large nuclei, sometimes containing inclusion bodies, are seen in the areas of demyelination.

Subacute cortical cerebellar degeneration. This condition is most common in adults and is manifested by progressive cerebellar signs and dementia. Death occurs within a few months. The disease is associated with carcinoma, most often of the bronchus, less often of the ovary or other organs. Frequently the neurological symptoms antedate evidence of the primary malignancy. Microscopic examination reveals loss of Purkinje cells of the cerebellar cortex, and there may be additional neuronal degeneration of the olives and subthalamic nuclei. Sometimes demyelination of the long tracts of the spinal cord occurs.

Inflammatory and Toxic Diseases of the Brain

These two etiological categories are grouped together because it may be both clinically and pathologically difficult to differentiate toxic from infectious inflammation of the brain. Intracranial infection may occur from infected paranasal sinuses, ears, or mastoids via emissary veins or from organisms in the blood stream.

FIGURE 31. Cerebral abscesses. Surrounding edema has displaced midline structures. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 51. Williams & Wilkins, Baltimore, 1964.)

Cerebral infection is, nevertheless, relatively infrequent because of the blood-brain barrier. The latter consists of the arachnoid, which forms the adventitia of the blood vessels, and the contiguous glial membrane composed of the sucker-like feet of astrocytes. This barrier is much more than an anatomic structure; it is primarily a neurochemical homeostatic mechanism. Focal breakdown in the blood-brain barrier may lead to spread of infection from blood to brain with abscess formation. Meningitis usually causes a more generalized disturbance of the blood-brain barrier and allows infection to spread to superficial areas of the brain.

Suppurative infections

Brain abscess. Sources of infection in the development of a brain abscess are the blood stream, carrying organisms from a distant site such as the lung; infected paranasal sinuses, mastoids, or ears; and fractures of the skull either through infected sinuses or penetrating injuries. The symptoms and signs of a brain abscess are similar to those of a neoplasm of the brain. Fever is often conspicuous by its absence, and inflammatory cells need not be present in the spinal fluid. The brain abscess may seal off and resolve; it may rupture to the surface or into a ventricle, causing meningitis; or it may result in sinus thrombosis. Antibiotics may be curative, but often surgical evacuation is necessary, particularly when the abscess acts as an expanding mass. The acute brain abscess appears as a pus-filled cavity surrounded by soft necrotic brain tissue and, beyond that, localized edema (Figure 31). More chronic abscesses are walled off by thick, firm, fibrous tissue. On microscopy, necrosis and inflammatory cells are obvious. The abscess is bordered by a wall of collagenous tissue built of fibroblasts (rather than glial cells) and new capillaries.

Dural abscess. Abscesses related to the dura usually produce signs of increased intracranial pressure, as well as focal cerebral signs. The patient shows clinical evidence of infection, but the spinal fluid reaction is that of an aseptic meningitis. These diseases require intensive antibiotic therapy and surgical evacuation.

Subdural abscess. A subdural abscess is most often secondary

to middle ear or paranasal sinus infections but may be related to dural sinus thrombophlebitis. Subdural empyema appears as a purulent exudate over the surface of the brain. Under the microscope, polymorphonuclear inflammatory cells make up a fibrous exudate.

Extradural abscess. An extradural abscess is usually secondary to frontal sinusitis or mastoiditis. It is more localized than a subdural abscess. Its gross and microscopic appearance is similar to the latter.

Sinus thrombosis. Sinus thrombosis is most often caused by extension of infection, particularly from the ears or paranasal sinuses, to the venous sinuses. Cavernous sinus thrombosis usually arises from infection of the face, nose, eye, or sphenoid or ethmoid paranasal sinuses. Transverse sinus thrombosis is commonly secondary to middle ear infection or mastoiditis. Superior longitudinal sinus thrombosis most often occurs from frontal sinusitis or is of marantic origin, i.e., secondary to debilitating disease in the very young or very old. Edema and congestion in the areas of the head and face drained by veins filling these sinuses are accompanied by fever and increased intracranial pressure. Antibiotic therapy is vital, but the role of anticoagulants is still in doubt. All forms of sinus thrombosis cause extensive venous congestion of the adjacent brain with scattered hemorrhages and softening of the parenchyma.

Meningitis. It is best to consider the meningitides under two large classifications; purulent or acute meningitis and nonpurulent or chronic meningitis.

Purulent or acute meningitis. Purulent meningitis is manifested by the sudden onset of headache and stiff neck, usually with nausea and vomiting, high fever, and often alteration in the state of consciousness. The spinal fluid is turbid; contains 1,000 to 15,000 white blood cells per cubic millimeter, predominantly polymorphonuclear leukocytes; and has elevated protein and low sugar. The gross appearance of purulent meningitis (Figure 14) is characterized by hyperemia of the meninges, and, first, the development of a fibrinous exudate and, later, a purulent exudate, within the subarachnoid space. The exudate follows cerebral sulci or vessels, or both, along the base and over the convexity of the brain. There may be associated blockage of absorptive surfaces of the meninges and/or obstruction of the foramina of the fourth ventricle with resultant hydrocephalus. If recovery occurs, the purulent exudate may organize into a thick, gray membrane. On microscopic examination, one sees numerous polymorphonuclear leukocytes and large mononuclear cells within the exudate. Engorgement of pial vessels is evident with associated extravasation of red cells. In the brain, perivascular infiltration of inflammatory cells is predominantly within the Virchow-Robin spaces. (These spaces surround the arteries and veins, but not capillaries, and may be considered an invagination of the subarachnoid space along the vessel walls.) The exudate may follow the blood vessels into the cortex, causing small microabscesses. With healing, organization occurs and fibroblasts with new capillaries form thick fibrous tissue.

The most common organisms causing acute purulent meningitis are the following. The Meningococcus (a gram-negative diplococcus) accounts for 40 per cent of all cases of purulent meningitis. Seventy-five per cent of the cases occur before the age of 10 years. Associated infection of the adrenal glands is

rare but accounts for the Waterhouse-Friderichsen syndrome with adrenal hemorrhage, shock, and death. The *Pneumococcus* (a gram-positive diplococcus) makes up 10 per cent of all cases of purulent meningitis and is associated with the highest mortality rate. Fifty per cent of these cases occur within the 1st year of life or after the 50th year of life. The *Hemophilus influenzae* (a gram-negative bacillus) accounts for 6 per cent of purulent meningitides and is primarily a disease of childhood, 90 per cent occurring before the age of 5 years. A large percentage of children recovering from this disease develop subdural effusions. The *Streptococcus* (a gram-positive coccus) is almost always secondary to a primary focus and makes up approximately 8 per cent of purulent meningitides. Other organisms causing purulent meningitis include the *Staphylococcus* (gram-positive), usually associated with a localized abscess; *Escherichia coli* (gram-negative), usually found in disease of the newborn or young children; and *Pseudomonas aeruginosa* (gram-negative), rarely a contaminant of a spinal tap.

Often the organism is not seen on initial staining of the spinal fluid, and sometimes the organism cannot be cultured. If the patient is under 6 years of age there is more than a 90 per cent chance that the organism is *Meningococcus* or *Hemophilus influenzae*, and treatment should consist of tetracycline or chloramphenicol, 50 mg. per kilogram per day in 4 doses. In older patients over 90 per cent of meningitides are due to *Meningococcus* or *Pneumococcus* and they should be treated with 1 million units of penicillin every two hours. It sometimes may be desirable to use both penicillin and, 3 to 4 hours later, chloramphenicol.

Chronic meningitis. The chronic meningitides are manifested by the gradual development of headache, stiff neck, malaise, and fever. Cranial nerve involvement is often present because of exudate at the base of the brain. The spinal fluid usually contains 50 to 500 white blood cells per cubic millimeter, predominantly mononuclear leukocytes, elevated protein, and low sugar.

Tuberculous meningitis. Tuberculous meningitis is by far the most common form of chronic meningitis. The gross appearance of this disease (Figure 15) is characterized by a pale glistening weblike exudate at the base of the brain. Sometimes miliary tubercles (grey-white nodules) may be seen in the cerebral sulci and fissures. Under the microscope, fibroblasts, lymphocytes, epithelioid cells, and giant cells are present in and around zones of necrosis. Large granulomas, tuberculomas, may act as slowly growing brain tumors. Treatment of tuberculous meningitis consists of streptomycin, 1 to 2 mg. per day; isonicotinic acid hydrazide, 20 mg. per kilogram per day; and *p*-amino salicylic acid, 12 gm. per day.

Torula meningitis, due to *Cryptococcus neoformans*, produces an exudate similar to that of tuberculosis at the base of the brain. The microscopic appearance is again that of an exudate of lymphocytes, fibroblasts, and, in addition, plasma cells and foreign body giant cells. The latter contain torula organisms which appear as small bodies surrounded by a thick, clear capsule. Granulomatous nodules of torula in the cerebrum may act as solid or cystic masses. Torula meningitis and other fungal meningitides, once invariably fatal, often respond to amphotericin B, administered by both the intravenous and intrathecal routes.

Other forms of chronic meningitis are distinctly less common. They are associated with syphilis (see below), actinomycosis, cysticercosis, trichinosis, and leprosy. Virus meningitides are usually benign. Lymphocytic choriomeningitis, and the meningitides of mumps, Coxsackie, and ECHO viruses are the most common. Sarcoidosis and carcinoma may invade the meninges and present a picture similar to that of a chronic infectious meningitis.

Sarcoidosis. Sarcoidosis is a systemic disease of uncertain

FIGURE 32. Encephalitis. Polymorphonuclear and mononuclear leukocytes infiltrate and surround a blood vessel within an area of disintegrating white matter. Hematoxylin and eosin. 250 X. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 77. Williams & Wilkins, Baltimore, 1964.)

origin characterized by granulomata composed of large epithelioid cells, unassociated with necrosis. The most common neurological involvement is paralysis of the facial nerve in association with uveitis and parotitis (uveoparotid fever). Optic neuritis and peripheral neuritis may occur. Granulomatous meningeal infiltration can cause an aseptic meningitis, but with low levels of spinal fluid sugar. Involvement of the base of the brain is associated with diabetes insipidus, and diffuse infiltration may cause any variety of diffuse or focal cerebral signs. Steroid therapy is very beneficial.

Encephalitis. Because the central nervous system reacts in a limited manner to irritating stimuli, either infectious or toxic, the nonsuppurative encephalitides have many pathological characteristics in common. The gross appearance (Figure 17) is that of slight to moderate meningeal congestion, and the underlying edematous, hyperemic brain tissue often reveals small hemorrhages. On microscopic examination (Figure 32), an inflammatory cellular infiltrate is seen within the tissue and perivascular spaces. Arteritis and petechial hemorrhages are present. There is demyelination and neuronal degeneration of varying degrees with microglial hypertrophy and proliferation. Inclusion bodies with neurones or glial cells suggest a virus origin.

Infectious encephalitis

Neurotropic viruses. Neurotropic viruses cause encephalitis that may be manifested by no more than headache and fever. The more severe, typical cases present additional features of somnolence, confusion, and, sometimes, delirium. Ocular signs and other focal signs may occur. Stiffness of the neck is common. Systemic involvement is manifested by malaise and upper respiratory tract or gastrointestinal symptoms. The spinal fluid may reveal leukocytosis of 25 to 250 cells per cubic millimeter, mostly lymphocytes. Some neuro-

tropic viruses invade and injure the basal ganglia more than other areas of the brain. Von Economo encephalitis in the 1920's was such a disease, and post-encephalitic parkinsonism frequently resulted.

In addition to the pathological characteristics described above, certain histological changes strongly suggest the specific virus of origin. Poliomyelitis is associated with anterior horn cell degeneration. In rabies encephalitis, Negri bodies (Figure 16) (oval, acidophilic inclusion bodies) are seen in the cytoplasm of neurones, particularly in Ammon's horn and in Purkinje cells. Japanese B encephalitis causes unusually marked destruction of the Purkinje cells of the cerebellum. Herpes simplex encephalitis is associated with intranuclear inclusion bodies and is predominantly focal. Other infections caused by neurotropic viruses include the equine encephalitides, St. Louis encephalitis, and herpes zoster encephalitis.

Viscerotropic organisms. Most other organisms causing encephalitis are viscerotropic and involve the nervous system as part of a generalized systemic infection. The following diseases are most common.

- i. Viral: Coxsackie, ECHO, herpes simplex, mumps, psittacosis
- ii. Bacterial: typhoid, paratyphoid, tetanus, botulism, diphtheria
- iii. Rickettsial: typhus, rocky mountain spotted fever
- iv. Spirochetal: syphilis, Weil's disease
- v. Protozoal: malaria, toxoplasmosis
- vi. Fungal: torulosis, coccidiosis, moniliasis
- vii. Caused by helminths: trichinosis, cysticercosis, schistosomiasis

The clinical picture of encephalitis associated with viscerotropic organisms is similar to that seen in encephalitis due to neurotropic viruses, with certain exceptions. The most common exceptions are syphilis, toxoplasmosis, and tetanus (see below).

Neurosyphilis. Neurosyphilis may be divided into those cases which affect predominantly the vascular and interstitial tissue of the CNS and those in which maximal disease is in the parenchyma, but these conditions are not mutually exclusive.

Parenchymal neurosyphilis is characterized by two major diseases, tabes dorsalis and general paresis. Both diseases occur many years after the primary infection. In both, miotic pupils unreactive to light (Argyll-Robertson pupils) are found, although less often in paresis than in tabes. The cerebrospinal fluid (CSF) reveals elevated protein and increased numbers of lymphocytes, as well as positive serology and abnormal colloidal gold curves, although in "burnt out" tabes the CSF is often normal.

General paresis occurs in 2 to 3 per cent of all patients with syphilis. Symptoms of progressive dementia with agitated, expansive, and/or depressive qualities occur 5 to 20 years after the primary infection. Slurred speech and minor tremors are common. On gross inspection old meningitis is manifested by thick opaque meninges, particularly over the convexity of the brain. The underlying brain is small, and wide sulci are further evidence of atrophy, predominantly in the frontal lobes. The microscopic appearance of general paresis is primarily that of neuronal degeneration within the frontoparietal cortex. There is associated long tract,

as well as patchy, demyelination. Subpial and subependymal glial proliferation is noted. Hypertrophied microglia are seen as elongated rod cells often filled with iron granules that stain brilliantly with Prussian blue. Small round cell perivascular infiltration and endothelial proliferation are also present.

Tabes dorsalis is chiefly characterized by demyelination of the posterior columns of spinal cord. The resultant position sense loss causes ataxia and associated loss of deep pain sensation may lead to the development of painless traumatic arthropathies (Charcot joints). Sometimes degeneration of the optic nerves causes blindness, and oculomotor nerve paresis is common. Pains are a prominent symptom. Lightning-like pains, usually in the extremities, and girdle pains or paresthesias are probably due to posterior nerve root disease. Crises of severe pain may arise from viscera.

In luetic arteritis, parenchymal involvement is secondary to thrombosis and infarction. Luetic meningitis presents the features of a chronic meningitis with thickening of the meninges at the base of the brain. Mononuclear cell infiltration is evident in arteritis and meningitis due to syphilis. A luetic granuloma (gumma) acting as a brain tumor is virtually extinct.

The therapy of choice for neurosyphilis is penicillin. A total dose of 6 million units is administered in divided dosage over a period of several days.

Toxoplasmosis. Toxoplasma often infects infants in utero and is manifested by hydrocephalus, convulsions, chorioretinitis, and intracranial calcifications. On microscopy, miliary granulomas of large epithelial cells and chronic inflammatory cells are seen. Intracellular as well as extracellular parasites appear as small acidophilic masses.

Presumably viral encephalitis. Other encephalitides are of indeterminate but presumably viral origin because inclusion bodies are found in brain tissue. They have an unusually poor prognosis.

Subacute inclusion body encephalitis usually begins in childhood or adolescence and ends in death after weeks or months. The electroencephalograms of these patients often reveal periodic slow waves and spikes (see Section 10.1).

Cytomegalic inclusion body disease begins in the fetus, is manifested in the newborn, and usually results in death after a few months. Inclusion bodies may be found in the cells of urinary sediment as well as the brain.

Acute necrotizing encephalitis sometimes follows a febrile illness and causes progressive focal signs often like those of a temporal lobe brain tumor. Death occurs within days or weeks. Intranuclear inclusion bodies are usually found in nerve and glial cells.

Progressive multifocal leukoencephalopathy (see above) may also present inclusion bodies in diseased cells of the brain.

Other encephalitides of presumably viral origin are associated with infectious mononucleosis, encephalomyocarditis, epidemic neuromyasthenia (Icelandic disease), and cat scratch disease. These diseases are usually benign.

Reaction to vaccination, etc. Some encephalitides are a reaction of the brain to vaccination, exanthemata (e.g., measles, chicken pox), rheumatic fever, or other systemic inflammations.

Acute disseminated encephalomyelitis affects grey matter predominantly. It occurs either during an infectious disease or a few days to 3 weeks after an infectious illness or vaccination. Recovery may occur.

Acute hemorrhagic leukoencephalitis, as the name implies, affects white matter predominantly. This disease often follows a febrile illness and ends in death after a few days. These two

illnesses may be acute allergic demyelinating diseases with secondary reactive inflammation.

Sydenham's chorea occurs in young adolescents or young primiparas (chorea gravidarum), but most frequently in children between 5 and 13 years of age. It is more common in females than in males. The onset may be manifested by no more than irritability or unusual restlessness. Choreiform movements of the extremities increase in prominence, and similar movements affect the face and tongue. Hypotonic weakness is common. Sometimes emotional symptoms increase to psychotic delirium. Bed rest in a quiet environment with judicious use of sedatives is the treatment of choice. The relationship to rheumatic fever is well known, and prophylactic penicillin is warranted. The pathogenesis of Sydenham's chorea is still in doubt, for vascular and degenerative mechanisms have been implicated as well as inflammatory disease.

Other inflammatory syndromes. These syndromes may affect the brain but are of unknown etiology.

Behcet's syndrome is manifested by recurrent uveitis and ulcers of mucous membranes. Meningoencephalitis occurs, and sometimes there is involvement of the brain stem or spinal cord.

Vogt-Koyanagi-Harada's syndrome is characterized by uveitis, deafness, and depigmentation of the skin and hair. Neurological manifestations are predominantly those of meningitis or encephalitis.

Reiter's syndrome is characterized by urethritis, conjunctivitis, and arthritis. Rarely, meningoencephalitis, cranial neuropathy, or other peripheral nerve involvement may occur.

Toxic encephalitis. The toxic encephalitides present evidence of generalized cerebral dysfunction.

In adults, symptoms of headache and dizziness are accompanied by lethargy, confusion, delirium, and other evidence of toxic psychosis. Convulsive seizures may occur, but focal signs are usually minimal. Fever may or may not be present. Systemic signs are dependent upon the offending agent. Acute toxic encephalopathy in children is manifested by the sudden onset of fever, nausea, vomiting, stupor, delirium, or convulsions. The child may be flaccid but more often manifests increased muscle tone with meningismus. The deep reflexes are hyperactive, and bilateral Babinski signs may be present. Pupils are often dilated, and papilledema may occur. Sometimes the spinal fluid is under elevated pressure, and often protein is increased although the cell count is normal or only slightly elevated. The severity of the disease and its sequelae are variable. In adults, and particularly in children, multiple factors may contribute to the acute toxic encephalopathy. The effect of the toxin itself, the high fever and its associated dehydration, the changes in serum electrolytes and other alterations in blood chemistry, the anoxia secondary to a convulsion or to respiratory deficits must all be considered. In the case of infection, e.g., pneumonia in a child, the neurological features are often obscured by the systemic effects of the disease.

The histological changes in toxic encephalopathies are similar to those described under encephalitis (see above). Although in some cases visible changes in the central nervous system may be minimal, neuronal damage is often more prominent in toxic encephalitis than in viral encephalitis. In addition, toxins may affect arteries to a greater extent than viruses. The resultant proliferation and swelling of endothelial cells (proliferative endarteritis) or degeneration of endothelium causes thrombosis or hemorrhage.

Endogenous toxins. Endogenous toxins are most commonly associated with uremia, diabetic acidosis, hepatic encephalopathy, eclampsia, and, less often, porphyria.

Convulsions and coma in parturient and postpartum women may be due to toxic or vascular factors. The comatose states associated with diabetes and uremia may be clinically distinguished by the odor of the patient's breath (acetone and urea, respectively). Kussmaul respirations may occur in both diabetic and uremic coma. With the latter, other types of respiratory abnormalities are common (e.g., Cheyne-Stokes respirations), and muscle twitching or convulsions may occur. Determination of the blood sugar and urea nitrogen will establish the diagnoses.

Hepatic coma or hepatic encephalopathy. This disorder is characterized by insidious impairment of mental processes, leading to stupor and coma. Sometimes delirium and other evidence of toxic psychosis occur. Asterixis is characteristic of impending hepatic coma. Liver function tests are abnormal, and blood ammonia is elevated, but the level of the latter does not necessarily coincide with the severity of the encephalopathy. The electroencephalogram often shows diffuse slow activity with bilaterally synchronous triphasic waves (see Section 10.1). Nonabsorbable broad spectrum antibiotics are administered by mouth in order to reduce bowel flora and thus decrease production of nitrogenous metabolites.

Porphyria. Porphyria is an inherited disorder of porphyrin metabolism. The most common form affects young and middle-aged adults, more often females than males. The disease is characterized by episodic bouts of abdominal pain, other visceral symptoms, and peripheral neuropathy; however, mental and emotional symptoms, as well as convulsive seizures, are not uncommon. Exacerbations may be precipitated by ingestion of alcohol or barbiturates. Porphobilinogen is found in the urine.

Encephalopathy caused by endogenous toxins is characterized by histological changes previously described, but certain features may predominate. In eclampsia, proliferative endarteritis and petechial hemorrhages are prominent. In uremia and hepatic encephalopathy, perivascular and diffuse demyelination is marked. Demyelination of peripheral nerves is the chief pathological feature of porphyria; changes in the CNS are those of neuronal disease.

Exogenous toxins. The exogenous toxins consist of those elaborated by bacteria (causing tetanus, diphtheria, and botulism); alcohol; drugs, particularly sedatives and tranquilizers; heavy metals; and organic poisons.

Tetanus. Tetanus is caused by the toxin of the *Clostridium tetani* (a gram-positive bacillus) acting on myoneural junctions and, in the central nervous system, on motor synapses. Symptoms usually occur 5 to 15 days after the patient has suffered a contaminated wound. There is first stiffness of jaw and neck muscles with tonic spasm (trismus), retraction of the corners of the mouth (risus sardonicus), and dysphagia. Rigidity gradually develops with severe and painful extensor spasms, especially of the trunk musculature. Spasms can be precipitated by minimal stimuli, and convulsions may occur. Consciousness is usually preserved. The spinal fluid is normal. Recovery is likely if the incubation period has been long and the patient has survived the 1st week of illness. Treatment of tetanus consists of isolation in a quiet room with appropriate sedatives and anticonvulsant medication. If the skin test sensitivity is negative, tetanus antitoxin should be given intramuscularly until clinical manifestations begin to subside. Penicillin is also recommended. Muscle relaxants (for example, mephenesin), administered intravenously, may be of value. Tracheostomy is sometimes necessary. Tetanus should be differentiated from tetany (see Section 10.4). The pathological features of tetanus are minimal, with some evidence of neuronal damage and petechial hemorrhages.

Habituating and addicting drugs. Morphine and heroin cause stupor; cocaine and dextroamphetamine produce excitement and

delirium; marijuana and lysergic acid diethylamide (LSD) evoke hallucinations (see Section 10.4). In the remarkably few pathological studies that have been carried out in cases of morphine poisoning, the changes are similar to those described under the anoxic poisons (see below). Most common of all toxins, of course, is ethyl alcohol, although methyl alcohol is much more toxic. Methyl alcohol, particularly, affects the ganglion cells of the retina and optic nerve fibers with resultant blindness.

Ethyl alcohol intoxication. Delirium tremens occurs in chronic alcoholics either associated with intercurrent infection or injury, or 8 to 24 hours after sudden withdrawal from alcohol. Fever, tachycardia, and diaphoresis are prominent. Delirium is severe, and visual hallucinations are vivid. Restlessness, sleeplessness, coarse tremors, and sometimes convulsions may cause exhaustion and death. The brain of a patient who has died of delirium tremens or (rarely) of acute alcoholic intoxication appears edematous and hyperemic with diffuse petechial hemorrhages.

Chronic alcoholic intoxication is manifested by slowly progressive dementia and ataxia with restlessness and tremulousness. Convulsions frequently occur. Peripheral neuropathy is common, optic atrophy less so. Gross atrophy of the brain is evident, and cortical neuronal loss in the cerebrum and cerebellum is seen under the microscope.

Marchiafava-Bignami disease is clinically indistinguishable from chronic alcoholic intoxication except that the former progresses to death within 4 to 6 years. It is most often associated with intoxication by Italian wines. The disease is characterized by demyelination of the medial portion of the corpus callosum. (See above for other diseases associated with alcoholism, e.g., Wernicke's encephalopathy.)

Anoxic toxins. Anoxic toxins prevent oxygen from reaching or being used by nerve cells. The chief offenders are anesthetics and hypnotics, carbon monoxide, cyanide, and war gases (hypoglycemia might also be included).

Barbiturate intoxication is manifested by the gradual development of coma, occasionally preceded by delirium. Depressed respiration is a prominent sign. The duration of coma has greater prognostic significance than its depth. Diffuse, fast activity in the electroencephalogram may be an important clue in establishing the diagnosis; determination of barbiturate levels in gastric contents, blood, or urine is definitive. Support of vital functions, particularly respirations, is the cornerstone of treatment; stimulants are of questionable value. In severe cases, peritoneal dialysis may be life-saving. The chief pathological feature of barbiturate and other anoxic poisoning is neuronal degeneration, particularly in those areas of the central nervous system most vulnerable to ischemia (see above).

Other drugs. Other drugs frequently encountered in toxic dosages are psychotropic agents, the hydantoins, and atropine and its related compounds. The hydantoins in toxic dosages cause ataxia by their effect on the Purkinje cells of the cerebellum. Atropine and its congeners produce central anticholinergic activity with mental symptoms of amnesia, hallucinations,

illusions of unreality, or delirium; and motor signs of weakness, ataxia, restlessness, excitement, or choreiform activity.

Psychotropic drugs. Psychotropic drug intoxication may cause neuronal damage, most pronounced in the basal ganglia, hypothalamus, and mesencephalon. The following outline, for the most part, refers to tranquilizers as exemplified by the phenothiazines. Most of the signs may also be associated with antidepressant drugs, either dibenzazepine derivatives or hydrazides (monoamine oxidase inhibitors). Where indicated (*) the features are peculiar to or predominant with the antidepressants.

I. Toxic effects on the nervous system

A. Neurological phenomena

1. Dyskinesias, or muscle spasms; parkinsonism, akathisia, dystonia; tetanus-like syndromes
2. Convulsive seizures
3. Lethargy, somnolence, fatigue
4. Other neurological symptoms (headache, dizziness, weakness)
5. EEG slow wave or paroxysmal abnormality
6. Peripheral neuropathy*

B. Mental and emotional reactions

1. Impaired psychomotor function
2. Restlessness and excitement
3. Confusion and delirium
4. Insomnia and bizarre dreams
5. Increase in schizophrenic symptoms or in depression

C. Autonomic and endocrine disturbances

1. Alteration of vital signs
 - a. Disturbed temperature regulation, especially hypothermia
 - b. Tachycardia more often than bradycardia
 - c. Depression of respiration
 - d. Hypotension, especially orthostatic*; hypertension with other compounds*
2. Anticholinergic symptoms: dry mouth and skin, tachycardia, dilated pupils, paresis or paralysis of the bladder or bowel, fever, mental and motor signs (see the text, above)
3. Altered sexual function
 - a. Inhibition of ejaculation and impotence in men, or paradoxically, increase in libido in women
 - b. Gynecomastia in men or lactation and menstrual irregularity in women
 - c. False positive pregnancy test
4. Other effects
 - a. Hyperglycemia
 - b. Nasal congestion; excessive perspiration*
 - c. Weight gain; peripheral edema

II. Systemic toxic reactions

A. Primary reaction

1. Cholestatic jaundice and xanthomatous biliary cirrhosis; liver cell disease*
2. Eosinophilia, hemolytic anemia, agranulocytosis, pancytopenia, thrombocytopenia
3. Contact dermatitis, skin photosensitivity
4. Pigmentary retinopathy, melanin pigmentation of the cornea and lens
5. Questionable teratogenic effects
6. Vagolytic quinidine-like effect in electrocardiogram
7. Shock following electroconvulsive therapy
8. Death due to overdosage

B. Secondary effect on other modalities

1. The potentiation of other drugs such as sedatives, narcotics, anesthetics, amphetamines, hypotensive agents, digitalis, insulin,* as well as the potentiation of alcohol and its complications

2. Sedation leading to hypostatic pneumonia and trophic ulcers
3. Inflammation or infection of the injection sites

The most common toxic effects of the phenothiazines are dyskinesias and anticholinergic reactions. Hypotension, especially of the orthostatic type, anticholinergic phenomena, and potentiation of other drugs (especially those causing hypertension) are the most frequent complications of antidepressant drugs.

Heavy metal poisons. Poisoning by mercury, arsenic, or lead may cause symptoms and signs affecting all portions of the central and peripheral nervous systems. In mercury toxicity, cerebellar signs are often predominant. Encephalopathy, neuropathy, or myopathy may be associated with arsenic poisoning. Chronic manganese poisoning may result in parkinsonism.

Lead poisoning is one of the most frequent exogenous poisons encountered in children and usually occurs when infants chew the paint off furniture or toys. (This activity in infants is not abnormal, but its persistence in older children is an expression of perverted taste sometimes seen in the mentally retarded.) The clinical features of acute lead encephalopathy are the same as those discussed under toxic encephalopathy of children (see above). The diagnosis of chronic lead intoxication can be made from roentgenograms of long bones where dense radio-opaque bands are noted below the proliferating zone of the epiphysis. Chelating agents (edathamil calcium dysodium) are judiciously used in treatment. Supportive therapy is, of course, vital, and symptomatic measures, including anticonvulsants, may be required.

Organic toxic compounds. These include carbon tetrachloride, certain mushrooms, and insecticides. Carbon tetrachloride affects both the central and peripheral nervous systems, but the primary pathological effects in the central nervous system are difficult to differentiate from the effects secondary to severe liver and renal disease. Mushroom poisoning may cause extensive cerebral damage. The insecticides containing organic phosphate derivatives, as well as drugs taken by patients for myasthenia gravis, produce their toxic effect by cholinesterase inhibition. This is manifested by muscarinic effects of abdominal cramps, lacrimation, and incontinence; nicotinic effects of fasciculations followed by generalized muscle weakness and paralysis; and central nervous system effects of headache, dizziness, ataxia, lethargy, convulsions, or psychic phenomena varying from excitation to depression.

Diseases of Early Life, Including Congenital and Metabolic Diseases

The process of embryonic maturation is so complex that one must marvel at the relative rarity of congenital malformations. Many defects are due to abnormality of the germ plasm, but trauma, infection, or chemical stimuli during early embryonic life account for a large number of malformations. Defects vary with the embryonic stage at which alteration in the maturation process occurs, with the site of neural involvement, and with the severity and type of the underlying disturbance. The process of birth itself is, of course, fraught with potential hazards, particularly traumatic and anoxic phenomena. Infections or other illnesses around the time of birth may cause irreparable damage. There has been rapid growth of knowledge in neurochemistry; many metabolic diseases responsible for physical and mental retardation or failure of infants to thrive have been recently found. Important genetic dis-

coveries have revolutionized concepts of certain congenital diseases.

Diseases of early life may be divided into those beginning before, during, or after birth. Except where indicated, these diseases are associated with varying degrees of physical or mental retardation. Convulsive seizures are not uncommon.

Prenatal malformations

Defects of the cerebral hemispheres. Anencephaly is the absence of the calvarium and cerebral hemispheres; it is, of course, incompatible with life. Porencephaly is characterized by large cavities within the cerebral hemispheres. Microcephaly is the reduction in the size of the cerebral hemispheres. Patients with agenesis of the corpus callosum need not manifest signs of disease.

Cervicocranial deformities. These malformations include craniostenosis (premature closure of cranial sutures), basilar impression (elevation of rim of foramen magnum into the cranial cavity), and Arnold Chiari malformation (displacement of the medulla and inferior cerebellum through the foramen magnum). Hydrocephalus is often associated with these and other defects of the occipitocervical junction.

Hydrocephalus. Hydrocephalus is the abnormal dilation of the ventricular system and, in the infant, is associated with head enlargement. It is usually due to congenital obstruction of the ventricular channels (e.g., stenosis of the aqueduct of Sylvius), but it is often seen in paranatal inflammatory diseases that prevent reabsorption of cerebrospinal fluid into the blood stream or in neoplastic diseases that obstruct the outflow of the cerebrospinal fluid. In addition to cervicocranial deformities noted above, hydrocephalus is often associated with congenital defects of the meninges, such as meningocele (failure of the envelope of the meninges to close fully at the midline) or meningomyelocele (failure of the neural tube to close fully, with splitting of the spinal cord and the meninges). The prognosis of hydrocephalus is related to its cause and severity. The process may stabilize with little or no clinical cerebral deficit. Surgery to shunt ventricular fluid around an obstruction or drain cerebrospinal fluid out of the cranial cavity is often indicated but may do no more than prolong a tragic vegetative state.

Syringomyelia and syringobulbia. These conditions are characterized by cavitation within the central portion of the spinal cord and medulla. Although one basis for this disease is thought to be congenital, symptoms may not begin until the 2nd or 3rd decade of life. In the typical case, loss of pain, but with preservation of touch sensations in the hands, precedes other signs of neuraxial involvement.

Mongolism. Mongolism is due to a chromosomal defect occurring in the fetus, often of mothers beyond the age of 40. It is characterized by idiocy and alterations of head and face as revealed by brachycephaly, flattened nose, slanting widely spaced eyes, and small ears. The bones, especially of the fingers, are shortened, and other deformities are common. Death is due to the effect of associated congenital anomalies, especially of the heart, or intercurrent infections. The gross configuration of the brain is more diagnostic than its microscopic appearance. There is reduction in the size of the cerebrum, with large simple convolutions. Under the microscope, alteration in nerve cells and their stratified architecture is seen.

Other chromosomal defects. Other chromosomal defects may be manifested as Klinefelter's syndrome (gynecomastia

FIGURE 33. Tuberosclerosis. The arrows indicate nodules of glial tissue projecting into the lateral ventricle. (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 221. Williams & Wilkins, Baltimore, 1964.)

FIGURE 34. Cerebral palsy. Ulegyria, right, next to a relatively intact gyrus on the left. Note that maximum shrinkage affects the deep aspects of the convolution. (From Blackwood, W., McMenemy, W. H., Meyer, A., Norman, R. M., and Russell, D. S. *Greenfield's Neuropathology*, ed. 2, p. 387. Williams & Wilkins, Baltimore, 1963.)

and aspermatogenesis in males) or Turner's syndrome (retarded growth and sexual development and webbed neck in females). Both of the above may exhibit mild mental retardation.

Tuberous sclerosis. This is a congenital disease sometimes inherited as a dominant factor. It is characterized by convulsive seizures, mental retardation, and sebaceous adenomas of the

skin. Death is rarely due to the neurological defects. On inspection of the brain, numerous pale nodules are seen projecting from the cortex or into the ventricles like the gutterings of a candle (Figure 33). (These nodules may be evident in air encephalograms.) On microscopy, the nodules reveal an alteration in the normal neuronal pattern with many giant-sized nerve cells. Demyelination is seen and fibrillary glial proliferation is especially prominent with astrocytes forming large multinucleated giant cells. Adenomas and myomas are found in other organs of the body.

Tuberous sclerosis is one of a group of neurocutaneous congenital diseases (phakomatoses). The others are Sturge-Weber disease (see above), Hippel-Lindau disease (see above), Recklinghausen's disease (neurofibromatosis), and ataxia telangiectasia (see above).

Perinatal illnesses

Cerebral palsy. Cerebral palsy may be due to a variety of causes, most commonly asphyxia or mechanical trauma at the time of birth. The premature infant is particularly vulnerable to these stresses, and the correlation of cerebral palsy with prematurity is high. There are many opportunities for the development of asphyxia during the birth process; breech delivery is the most common example. Trauma may cause intracerebral, subdural, subarachnoid, or intraventricular hemorrhages; contusions or lacerations of the brain; or tears of the dural sinuses or tentorium. Some think that venous congestion is a significant etiological factor in cerebral palsy, and others believe that arterial compromise during the birth process is an important mechanism. The manifestations of cerebral palsy depend upon the site of maximum damage. Disease of the cerebral hemispheres and cortex causes bilateral spastic weakness. Lesions of the basal ganglia result in dyskinesias (athetoid or choreiform). Defects of the cerebellum are associated with hypotonia and ataxia. The severity of neurological signs is extremely variable, and mental retardation may or may not be an associated feature (see Section 10.4 for discussion of mental retardation and minimal brain dysfunction).

After the initial insults to the brain have healed, pathological characteristics of birth injury may be noted. Ulegyria is manifested by shrunken gyri, with maximum atrophy of their walls deep within the sulci and relative sparing of their crowns (Figure 34). These gyri are found particularly in zones of the brain between main arterial territories or within one arterial distribution. Sclerosis, rarification, or cavitation of the white matter adjacent to the lateral ventricles is another distinctive feature of cerebral palsy. Atrophy of the basal ganglia, especially the caudate nucleus, is frequently seen in these brains.

Status marmoratus or *état marbre* is a congenital disease clinically manifested by athetosis. The histopathology is characterized by excessive myelination between the caudate and lenticular nuclei, with patchy degeneration of neurones in the basal ganglia and associated replacement by glial tissue. The disease is not always a result of birth injury.

Failure to thrive. This term is used to denote lack of normal physical and mental growth development during infancy. The cause of this condition is often obvious, for gross congeni-

tal malformations, severe feeding problems, and chronic infections will almost invariably be associated with this phenomenon. Sometimes more subtle defects may be the cause. Poor care by the mother, emotional or social deprivation, poor nutrition, chronic intoxication, or low grade infection may be underlying factors. Specialized examination may be required to find genetic factors or enzyme or metabolic deficiencies, such as the malabsorption syndromes or endocrinopathies. Last, but not least, any disease of the brain may result in failure to thrive. Occult chronic subdural hematoma secondary to trauma or subdural effusion following meningitis must be prime considerations.

Kernicterus. See below.

Postnatal diseases

Leukodystrophies. Leukodystrophies are demyelinating diseases of the brain, beginning in infancy, usually familial and invariably fatal. The illnesses are characterized by dementia, progressive paralysis, and ultimate decerebrate rigidity. The pathogenesis of these diseases is unknown, but they may be related to the lipoidoses (see below). The primary pathological lesion is diffuse and symmetrical degeneration of cerebral white matter. Loss of axis cylinders is usually commensurate with the degree of demyelination.

Epithelioid or globoid cell leukodystrophy (Krabbe's disease). This disease begins in infancy and runs a course of 1 or 2 years. Within demyelinated areas are groups of mononuclear epithelial-like cells and larger multinucleated globoid cells. Both types of cells occur most commonly near or around small blood vessels.

Metachromatic leukoencephalopathy (Greenfield's disease). This illness often begins between 1 and 2 years of age and has a course of 2 to 3 years; when beginning in late childhood, its duration is somewhat more prolonged. Prominent metachromatically staining (i.e., staining a tint different from that of the stain employed) lipids occur in irregular granular masses, both intracellular and extracellular, within demyelinated white matter. The metachromatic lipids are also found in the epithelium of renal tubules, and the diagnosis can be made during life by examination of the urinary sediment.

Sudanophilic leukoencephalopathy. This includes Merzbacher-Pelizaeus disease. The illness is more common in males than females, often begins after 1 year of age, and has a very chronic course. It is distinguished from other leukodystrophies by the predominance of sudanophilic neutral fat in the myelin breakdown products.

Spongy degeneration of the white matter. This condition begins in infancy and results in death after 6 months to 2 years. Macrocephaly is often present. In this disease the white matter is replaced by a meshwork of axons and glial fibers which surround cystic areas.

Neuronal disease

Kernicterus. Kernicterus is caused by severe neonatal hyperbilirubinemia, usually due to maternal-fetal blood incompatibility and associated erythroblastosis foetalis. It is manifested during the first 2 weeks of life. Lethargy, opisthotonus, and seizures are common, in addition to jaundice. If the infant survives, extrapyramidal signs and mental deficiency occur, often with deafness. Exchange transfusions with Rh-negative blood during the first 4 to 5 days of life are the best prophylaxis. The chief pathological features are bile pigmentation of nerve cells and their associated destruction. The disease affects predominantly

subcortical nuclear structures, particularly the subthalamic nucleus, Ammon's horn, and the globus pallidus (Figure 18). There is associated patchy demyelination and gliosis.

Werdnig-Hoffman disease. This disease is manifested by progressive spinal musculature atrophy, with flaccid weakness, beginning during the 1st year of life. Death usually occurs within a few months or years, but occasionally the disease becomes static and the patient may live to adulthood. Loss of anterior horn cells is the major pathological finding.

Hallervorden-Spatz disease. This is a rare familial illness characterized by progressive rigidity, choreoathetosis, and mental deterioration. It begins between 5 and 10 years of age and progresses to death after 1 or 2 decades. Under the microscope, deposition of iron pigment is seen in neurones, glial cells, and extracellular spaces. The globus pallidus and substantia nigra are particularly affected.

Alpers disease. Alpers disease is a rare illness of infancy, sometimes familial. Convulsions, mental impairment, spasticity, and extrapyramidal and cerebellar signs progress to death within a few years. The characteristic pathological feature is degeneration of grey matter, most severe in the middle layers of the cerebral cortex, but also affecting most other neuronal structures of the brain.

Metabolic diseases of infancy

Diseases of fat metabolism (lipoidoses). In these illnesses products of abnormal metabolism accumulate in nerve cells, usually displacing the nucleus and interfering with neuronal function. Diagnosis can be made during life by microscopic examination of autonomic nerve cells found in the biopsy of rectal mucosa.

Amaraotic familial idiocy: The infantile form (Tay-Sachs disease). Tay-Sachs disease begins between the 4th and 8th month of life and usually occurs in Jews. It is characterized by blindness, mental deterioration, convulsive seizures, spasticity, hyperkinesia, and, eventually, opisthotonus. A cherry red spot is seen in place of the macula. Death occurs within a few months to 3 years. Deposition of fine fat granules in the cytoplasm (Figure 35) is responsible for swelling of nerve cells particularly in the cortex of the cerebrum and cerebellum. Similar but less prominent changes are noted in microglia. The excessively deposited metabolic products are gangliosides.

Variants of this disease include a late infantile form (Bielchowsky), a juvenile form beginning between 3 and 10 years of age (Batten-Spielmeyer-Vogt), and an adult form (Kufs). These diseases differ from Tay-Sachs disease in that predilection for Jews is not evident, their courses are subacute or chronic, and retinal lesions may be absent or pigmentary degeneration of the retina may occur rather than a cherry red macular spot.

Niemann-Pick disease. This disease occurs most often in Jewish infants, and its neurological features are also very similar to, or indistinguishable from, Tay-Sachs disease. In Niemann-Pick disease, however, systemic involvement (hepatosplenomegaly) is present. The fatty products of abnormal metabolism are stored in the reticuloendothelial system of the body, as well as in the neurones of the CNS. The resultant large foam cells are filled with sphingomyelin and cholesterol.

Gaucher's disease. Gaucher's disease is a familial illness that usually begins in the 4th to 6th month of infancy but may occur in later life. It is characterized by mental retardation,

FIGURE 35. Amaurotic familial idiocy. Lipid deposition swells the cytoplasm of neurons (in this case, anterior horn cells of the spinal cord) and crowds the Nissl substance around the nucleus. Thionin. 350 \times . (From Blackwood, W., Dodds, T. C., and Sommerville, J. C. *Atlas of Neuropathology*, ed. 2, p. 9. Williams & Wilkins, Baltimore, 1964.)

bulbar palsy, opisthotonus, and enlargement of the spleen and liver. Death occurs during the 1st year. The lipids, cerebrosides, are stored in the cells of the reticuloendothelial system (spleen, liver, and bone) much more than in nerve cells, but neuronal degeneration is, nevertheless, a common feature.

Gargoylism. Gargoylism is a chronic familial disease beginning at the end of the 1st year of life manifested by mental deficiency, corneal opacity, dwarfism with large skull, and hepatosplenomegaly. The lipid deposits in cells of the brain and other organs are probably gangliosides.

Hand-Schüller-Christian disease. This is a chronic illness that begins between infancy and 5 years of age. It is characterized by bony defects, especially in the skull, affecting predominantly the orbit, pituitary fossa, and adjacent floor of the third ventricle, causing exophthalmus and diabetes insipidus. The bony lesions are granulomas of foam cells containing cholesterol esters. The lesions compress brain tissue, but the neurones themselves are not primarily affected.

Diseases of carbohydrate metabolism

Gierke's disease. This is a glycogen storage disease primarily affecting the liver and kidneys, but not nerve cells. Convulsive seizures may be associated with bouts of hypoglycemia and ketosis. A variant of this disease is sometimes associated with neuronal damage.

Galactosemia. Galactosemia is a familial disease seen in infants several weeks or months after birth. The illness is manifested by jaundice, hepatomegaly and cataract formation, as well as mental retardation and convulsive seizures. Increase in galactose in the blood and urine is due to the infant's inability to utilize the breakdown products of milk digestion. Withdrawal of milk at the earliest age is beneficial.

Diseases of protein metabolism

Phenylketonuria. This is a familial disease, beginning during the first few weeks of life, and is most common in blond, blue-eyed babies. It is characterized by physical and mental retardation and sometimes convulsive seizures. This disease is caused by a defect

in the enzyme required for oxidation of phenylalanine to tyrosine. One of the alternate metabolites, phenylpyruvic acid, can be detected by the green color produced when acidified urine is tested with 5 per cent ferric chloride. If diets designed to lower blood phenylalanine are instituted during the first few months of life, prognosis for near normal intelligence is good. On microscopic examination of the brain, defective myelination and associated gliosis are noted.

Maple syrup urine disease. This condition is noted between 5 and 10 days of life and is manifested by mental retardation, spasticity, myoclonic seizures, and a characteristic odor of

TABLE I
Other Diseases of Childhood and Adolescence

Almost Invariably of Childhood	Usually of Childhood	Often of Childhood or Adolescence
<i>I. Tumors</i>

		Kleine-Levin syndrome

^a Or of adolescence.

urine, as indicated by the name. Valine, leucine, and isoleucine are elevated in the blood. Dietary treatment may be beneficial, but death usually occurs within weeks or months. Demyelination is the predominant pathological feature.

Other diseases. More than a dozen other diseases are associated with amino aciduria or elevated amino acid levels in the blood. One of the most common of these diseases is histidinemia.

Diseases discussed under other categories. An overlap in this classification of "diseases of early life" with other etiological categories is inevitable. Thus, the leukodystrophies can be considered degenerative diseases. Certain infectious processes (e.g., toxoplasmosis) and some vascular diseases (e.g., Sturge-Weber disease) are congenital. Many cases of cerebral palsy are of traumatic origin. Tuberous sclerosis might be considered under tumors although it is not a truly neoplastic disease. Table I lists diseases of children discussed under other etiological classifications for greater clarity of presentation.

10.4 OTHER NEUROLOGICAL SYNDROMES

SEYMOUR SOLOMON, M.D.

Dysfunction of the Nervous System

There are several diseases characterized by pathophysiological phenomena rather than well defined or consistent neuropathology. These diseases may be particularly confused with psychogenic disorders.

Dysfunctions of the motor system manifested by hypotonia and weakness

Myasthenia gravis. Myasthenia gravis occurs most commonly between the ages of 20 and 40 years and af-

fects females more often than males. It is probably due to a defect in the metabolism of acetylcholine or to excessive activity of cholinesterase at the motor end plate. There is an increased incidence of disease of the thymus and thyroid glands in myasthenia, and autoimmune interrelationships have been postulated. The disease is characterized by excessive fatigability and weakness, predominantly of those muscles innervated by the cranial nerves. The extremities, especially the upper extremities, are involved to a lesser extent. Double vision, ptosis, dysphagia, and difficulty in chewing are common initial symptoms. Spontaneous remissions sometimes occur, but usually intermittent progression is noted. The diagnosis is established if brief disappearance or improvement of signs occurs within 30 seconds of an intravenous injection of edrophonium (Tensilon). Maintenance therapy consists of neostigmine or pyridostigmine (Mestinon), but some of the toxic effects of these cholinesterase inhibitors (see Section 10.3) may simulate an exacerbation of myasthenia. Thymectomy is of benefit in the early stages of the acute disease in young females.

Periodic paralysis

Hypokalemic (familial) periodic paralysis. This condition begins in adolescence and affects males more than females. It is manifested by recurrent bouts of flaccid weakness or paralysis of somatic musculature, usually sparing muscles innervated by the cranial nerves and muscles of respiration. The symptoms persist for 2 to 24 hours. During the attack there is loss of deep tendon reflexes and of muscular response to electrical stimulation. The episodes usually occur during rest and may be precipitated by a high carbohydrate meal, alcohol, insulin or adrenocortical hormones. The paralysis is associated with a drop in the serum potassium and corresponding electrocardiographic changes (depressed S-T segment and diminished amplitude of T wave). On the other hand, change in serum potassium is not invariable and need not correspond with the course of the paralytic attack. The disease is not progressive. Treatment consists of the administration of potassium during the attack and the prevention of precipitating factors.

Hyperkalemic periodic paralysis (adynamia episodica hereditaria). This condition is on the other end of the spectrum of primary defects of potassium metabolism. As differentiated from familial (hypokalemic) periodic paralysis, the hyperkalemic bouts of paralysis usually begin in the 1st decade of life, affect both sexes equally, are of short duration, and are associated with paramyotonia. Distinction can be made with certainty by determination of the serum potassium level during an attack. The electrocardiogram affords most rapid evaluation of hyperkalemia (prolongation of the Q-R-S interval and T wave elevation). The attack is treated by administration of intravenous calcium.

Finally, periodic paralysis may occur without change in potassium levels and may be associated with spontaneous episodes of hyponatremia.

Dysfunctions of the motor system manifested by hypertonia and weakness

Myotonia. Myotonia is characterized by prolonged muscle contraction in spite of attempted muscle relaxation. It is most often seen as part of myotonic muscular dystrophy (myotonia dystrophica). The latter is a hereditary disease beginning in young adults manifested by myotonic impairment of motor function (see Section 10.1) and dystrophic muscle wasting of the face, neck, and extremities. Associated features include

premature baldness, cataract formation, testicular atrophy, and other endocrinopathies, as well as mental deterioration. Myotonia congenita is a variant of myotonia dystrophica. Paramyotonia is the occurrence of this peculiar muscular reaction in association with cold. Treatment with procainamide or quinine may diminish myotonic phenomena.

The stiff man syndrome. This syndrome is characterized by bouts of severe rigidity and spasm of somatic musculature, lasting hours or days, often precipitated by minimal physical or emotional stimuli. The muscular spasms may or may not be painful. Trunk musculature is particularly involved, and the abdomen may be boardlike during an attack. When generalized, the syndrome resembles tetanus. The mechanism of this condition is unknown, but diazepam (Valium) decreases the severity of muscle contractions.

Torticollis. Torticollis is the unilateral contraction of cervical muscles, predominantly the sternocleidomastoid, twisting the head to one side. This disease may be a manifestation of dystonia musculorum deformans or drug toxicity, especially phenothiazine derivatives. Some believe that most cases of torticollis are fragments of a pathophysiological process akin to torsion dystonia, whereas others believe that the majority have a psychogenic mechanism. Results of medical or psychiatric therapy are poor, but spontaneous remissions are common.

Disease or dysfunction of the diencephalon associated with disorders of sleep or disturbance of autonomic function

Narcolepsy. The narcolepsy syndrome begins in youth or early adult life and affects males much more than females (6:1). Obesity is often present. The syndrome has four main features, although some patients never exhibit more than one. Narcolepsy, the most common feature, is manifested by sudden irresistible desire to sleep while sedentary. Sleep may last from a few minutes to a half hour. Cataplexy is impairment of muscle tone associated with sudden emotional stimulus; it may be manifested by no more than slight buckling of the knees. Total flaccid paralysis occurring immediately upon awakening from sleep, or less commonly, during the transition from drowsiness to sleep, is termed sleep paralysis. The latter lasts only a few seconds but is always frightening. Hypnagogic hallucinations are unusually vivid though brief. The disease is presumably due to dysfunction of the diencephalic reticular system. Narcoleptic sleep and other features of the narcolepsy syndrome are associated with the phenomena of rapid eye movement sleep and appear to be exaggerations of normal physiological events. (We may normally experience sleepiness while sitting quietly, weakness during fright or immediately upon arousing from sleep, and hallucinations (dreams) during sleep.) Treatment with amphetamines or other stimulants is beneficial, but patients with this syndrome may need much more than the average dose.

Akinetic hypersomnia, akinetic mutism, or coma vigil. These are different names for one condition. The patient is mute and immobile, but his eyes may follow people about the room or may be diverted by sound. A painful stimulus sometimes evokes reflex withdrawal or feeble movements, but without manifestations of pain or other emotion. The patient may swallow when fed but does not always chew food. Incontinence

of urine and feces is common. Duration of sleep is greater than normal, but the patient is easily aroused. In contrast to psychotic withdrawal, there is no evidence of negativism or catatonia, although during recovery, if it occurs, the patient may show these symptoms. Akinetic mutism is associated with organic disease of the midbrain diencephalon (especially caudal hypothalamus) and is presumably due to incomplete interruption of the reticular activating system.

Kleine-Levin syndrome. This is a rare disorder of males 10 to 25 years of age. It is characterized by periods of ravenous appetite soon associated with extreme somnolence lasting for days or weeks. An acute illness, fatigue, or headache may precede the episode. During an attack, behavior is disturbed; hyperirritability and uninhibited sexual activity occur. There may be impaired thought processes and hallucinations. Upon recovery, depression of spirits is occasionally noted. The pathophysiological site of this disease is presumed to be hypothalamic and/or prefrontal.

Riley-Day syndrome or familial dysautonomia. This is a rare condition noted during the 1st year of life, usually in Jewish children. The disease is characterized by blotchy skin, defective lacrimation, and excessive perspiration and salivation. Further dysfunction of the autonomic nervous system is manifested by intermittent hypertension with postural hypotension and defective temperature control. The infants feed poorly and frequently vomit. Neurological examination often reveals evidence of both mental and physical retardation as well as emotional instability. Incoordination and indifference to pain may be present. Corneal ulceration and systemic illnesses are common.

Fluid-electrolyte disorders

Water and sodium alterations. Dehydration may cause personality changes progressing to delirium. Lethargy, convulsions, then coma may occur. Hyponatremia is usually associated with dehydration. Overhydration also evokes the above symptoms. In addition, increased intracranial pressure, generalized weakness, and muscular cramps or twitching may be noted. Sodium depletion, often associated with water intoxication, frequently causes nausea and vomiting and signs of shock.

Pseudotumor cerebri, or benign intracranial hypertension, is usually due to cerebral edema, although in the past it was more often considered to be posttotic hydrocephalus, low grade intracranial inflammation having caused venous sinus obstruction. The disease is characterized by increased intracranial pressure with headache and papilledema. The mechanism for this disturbance of cerebral homeostasis is unknown, but metabolic factors are indicated by the high incidence of this condition in adolescent girls or young women who are obese and often have menstrual dysfunction; decreased adrenal function has also been implicated. Other causes of increased intracranial pressure and papilledema must always, of course, be considered (see Section 10.1).

Alkalosis and acidosis. Respiratory acidosis (CO_2 narcosis), due to hypoventilation, results in drowsiness and weakness. Increased intracranial pressure due to vasodilatation may occur. Metabolic acidosis is most commonly associated with diabetic coma and uremia. The hyperpnea of Kussmaul breathing accompanies lethargy, progressing to stupor and coma. Respiratory alkalosis, caused by hyperventilation, frequently produces symptoms of lightheadedness, feelings of unreality, paresthesias, palpitation, drowsiness, tremulousness, tremors, and, finally, tetany. The latter is manifested by carpal spasm, laryngospasm, and neuromuscular irritability as demonstrated by Trousseau's and Chvostek's signs. If tetany is severe, convulsions may occur. Metabolic alkalosis, often due to excessive vomiting, is associated with hypoventilation, apathy or delirium, generalized weakness, and tetany.

Potassium disorders. Excessive serum potassium causes flaccid paralysis (see adynamic episodic hereditary, above), paresthesias, and lethargy. Arrhythmias and cardiac arrest may

occur. Hypokalemia results in flaccid paralysis of somatic musculature (see familial periodic paralysis, above) as well as paralytic ileus; lethargy may be prominent. Sometimes cardiac arrhythmias as well as heart failure occur.

Magnesium alterations. Excess serum magnesium is associated with lethargy, decreased neuromuscular responsiveness, respiratory failure, and finally, coma. Magnesium depletion causes paresthesias, irritability, and delirium. Muscular weakness, twitching, coarse irregular tremors, tetany, or convulsions may occur, and cerebellar as well as basal ganglion signs have been reported. Cardiac arrhythmias may develop.

Endocrine disorders

Parathyroid and calcium. Hyperparathyroidism is associated with hypercalcemia and resultant hypotonic weakness and bone and muscle pains. Personality changes, delirium, dementia, and coma may occur. Osteomalacia is seen in roentgenograms of bones. Hypoparathyroidism causes hypocalcemia, with hyperreflexia, muscular weakness, tetany, or convulsions. Paresthesias are common. Mental changes may range from "nervousness" to frank psychosis. Cataracts form when the disease is chronic, and cerebellar or basal ganglia signs may be noted. Osteoblastic changes in bone and sometimes calcifications in basal ganglia are evident in roentgenograms.

Pancreas. Hyperinsulinism is initially manifested by anxiety, hunger, weakness, palpitation, shortness of breath, and perspiration. Then tremor, irritability, increasing confusion, delirium, or frank psychosis may occur. Muscular twitching or spasms, convulsive seizures, coma, and decerebrate rigidity are the final signs. The cerebral symptoms of diabetes are related to premature atherosclerosis. Diabetic coma has been noted above (acidosis).

Thyroid. Hyperthyroidism causes dyspnea and tachycardia. Myopathy and ophthalmoplegia may occur with or without exophthalmos. Tremor is common, and choreiform movements or convulsions may develop. The disease is associated with emotional symptoms of anxiety, lability of affect, irritability, and agitation, although apathetic hyperthyroidism rarely occurs. Thyroid crisis may result in acute delirium and other symptoms of toxic psychosis. Myxedema is associated with lethargy and weakness. The skin, especially of the face, is dry and puffy; the hair, thin and brittle. There is decreased psychomotor activity, and personality changes are common, especially depression. Memory and perceptual impairments are the chief signs of dementia. Headache and dizziness, dysarthria, and hoarseness are often present. Myopathies may affect the extremities, and pseudomyotonic reflexes can be frequently elicited.

Adrenal glands. Primary (hyper-) aldosteronism, a dysfunction of the adrenal cortex, causes hypertension with potential cardiac and cerebral complications. Muscular weakness or cramps, paresthesias, and headaches are common symptoms. Polyuria and polydipsia may occur. There is associated hypokalemia, hypernatremia, and metabolic alkalosis. Hyperadrenocorticism (Cushing's syndrome) causes symptoms of weakness and fatigability. Personality changes are not uncommon. Obesity of the face, neck, and trunk with purplish striae are characteristic of this condition. Amenorrhea, hirsutism, and loss of libido also occur. These patients frequently develop diabetes mellitus and hypertension. Pheochromocytoma is a tumor of the adrenal medulla causing paroxysms of hypertension, with associated symptoms of anxiety, tremulousness, perspiration, palpitation, and headache. In addition there may be dizziness, paresthesias, pallor and coldness of extremities, and nausea and vomiting. Cerebral hemorrhage is a potential complication. Addison's disease, decreased function of the adrenal cortex, is manifested by progressive fatigue, asthenia, and weakness. Syncope or shock and sometimes tremors or convulsions may occur. Irritability, apprehension, and personality changes are common. Abdominal distress, hypotension, and pigmentation of skin and mucosa are characteristic of this disease. Adreno-

genital syndrome, adrenal hyperplasia, is associated with virilization in children (congenital form) or virilization in women and sometimes feminization in men (acquired form, e.g., adenocarcinoma). There are no primary neurological symptoms.

Pituitary. Hyperpituitarism due to an eosinophilic adenoma (see Section 10.3) in an adult causes acromegaly, characterized by bone overgrowth, especially of the hands, feet, and mandible, and enlargement of the nose, lips, and tongue. Muscular weakness and personality changes frequently occur. The tumor in children is manifested by gigantism. Very rare basophilic adenomas are associated with Cushing's syndrome (see above). Hypopituitarism causes apathy and asthenia, lethargy, and fatigue. The facies is often bland; the skin waxen, pale, and dry; the body free of hair. There is associated hypofunction of other endocrine glands (especially ovaries and testes), hypothermia, and hypotension. This condition in children results in dwarfism. Minor emotional symptoms are common, but depression and frank psychosis sometimes occur. Crises may cause delirium, convulsions, or coma.

Epilepsy

Epilepsy is a recurrent paroxysmal disturbance of cerebral function manifested by somatic, visceral, and/or psychic phenomena usually associated with loss or alteration of consciousness. In years past the epilepsies were classified as idiopathic (essential, cryptogenic) or genetic and as acquired or symptomatic. As more and more knowledge about this subject has been attained, fewer forms of epilepsy have been classified as idiopathic, and this term has little practical value. It has been more useful to name the convulsive disorders by their clinical manifestations, hence the terms grand mal, petit mal, and psychomotor. More recently epileptic seizures have been classified by correlating pathophysiological (electroencephalographic) with clinical phenomena. Under this system of classification, all forms of epilepsy are divided into two groups, partial or focal seizures and generalized seizures (see Section 10.1 for electroencephalographic (EEG) patterns associated with the convulsive disorders).

Partial or focal seizures. These seizures are manifested in the electroencephalogram by discharges that are more or less anatomically localized and arise in cortical or subcortical regions. Organic cerebral diseases usually cause these convulsive disorders, although constitutional factors may be important. Seizures of this type may occur in children, but the incidence increases with age. Partial seizures are divided into those with elementary symptomatology, those with complex symptomatology, and those which begin in a focal manner but become secondarily generalized.

Seizures with elementary symptomatology. Partial seizures of elementary symptomatology are usually motor in character and unassociated with loss of consciousness. They often consist of focal clonic movements involving part or all of the musculature on the side contralateral to the discharging cerebral focus. Adversive seizures are manifested by turning of the head, eyes, and body away from the side of the discharging lesion. Less common focal motor seizures include inhibitory seizures, characterized by focal loss of tone and strength, or seizures that involve speech, either arrest of speech or forced vocalization. Other partial seizures of an elementary type are of a sensory nature. These may be somatosensory phenomena, e.g., local pain over some part of the contralateral face, body, or extremities. Visual, auditory, olfactory, and gustatory symptoms may occur either as an aura of a more generalized seizure or as an isolated

seizure state. Vertiginous phenomena are sometimes of epileptic origin. Autonomic symptoms, occurring in a paroxysmal fashion, are classified as partial seizures of elementary symptomatology. Episodic abdominal pain (abdominal epilepsy) is the most common form.

Seizures with complex symptomatology. Partial seizures with complex symptomatology reveal electroencephalographic abnormality of unilateral or asynchronous bilateral discharges, primarily involving the temporal or frontotemporal areas. These seizures often begin with the simple motor or sensory phenomena described above, and then alteration of consciousness or mental status invariably occurs. Some seizures may be manifested only as impaired consciousness. Others may involve mental and psychological symptomatology with intellectual alteration (e.g., amnesia or forced thinking); illusions or hallucinations (including altered awareness of self and *déjà vu* phenomenon); affective symptoms (e.g. fear or forced laughing); or psychomotor manifestations (automatisms), i.e. psychomotor seizures (see below). These phenomena may occur individually or in various combinations.

Seizures that become secondarily generalized. Partial seizures with either elementary or elaborate symptomatology may progress to generalized seizure activity. Jacksonian seizures begin as focal motor activity in one extremity, spread over the entire side, and, finally, become generalized (grand mal). Sometimes this progression is so rapid that the focal qualities may not be apparent. The secondarily generalized seizures may be symmetrical or asymmetrical, tonic or clonic. During the seizure, the electroencephalographic activity from the discharging focus rapidly becomes (secondarily) generalized.

Generalized seizures. Generalized seizures are presumed to arise in the diencephalon, because the EEG seizure discharges appear from all areas of the cerebral cortex in a bilaterally symmetrical and synchronous fashion. Loss or alteration of consciousness is almost invariable. It is these seizures which have been most often termed "idiopathic," for frequently an organic defect cannot be found. On the other hand, toxic or metabolic disturbances, as well as diffuse or scattered organic cerebral disease, may cause generalized seizures. Those seizures for which an organic cause cannot be found usually occur in children, but at any age seizures may be due to an organic or metabolic defect. This group is subdivided into nonconvulsive and convulsive seizures.

Nonconvulsive seizures. Nonconvulsive generalized seizures are usually manifested as simple loss or impairment of consciousness, i.e. petit mal. The seizure (*absence*) is brief, often momentary, and begins and ends abruptly without aura or sequelae. Petit mal usually begins in children after the age of 5 years (not before 2 years of age) and subsides after puberty. The EEG reveals rhythmic bilaterally synchronous and symmetrical 3 per second spike and wave discharges. Atypical forms of *absence* are usually associated with less classical spike and wave discharges. Petit mal status is characterized by a semistuporous state and, in the EEG, by more or less continuous activity of rhythmic 3 per second spike and wave forms,

or similar but less characteristic activity. Nonconvulsive seizures may be manifested by impairment of consciousness associated with other phenomena including (1) very mild clonic components, (2) increase or alteration of postural tone, (3) diminution or abolition of postural tone (drop attacks or atonic seizures), (4) slight automatisms (primarily movement of the mouth, lips and nodding of the head), or (5) autonomic phenomena (e.g., abdominal distress or sphincteric impairment).

Convulsive seizures. Those generalized seizures characterized by convulsive activity are classified by their motor signs. Infantile spasms are brief myoclonic jerks that involve the entire body, either in flexion or extension. The electroencephalogram reveals polyspike and slow wave activity occurring in a haphazard fashion from all areas of the head (hypsarrhythmia). The clinical and electrical phenomena disappear after the first few years of life, but signs of cerebral disease are usually permanent. Fragmentary myoclonic jerks may occur at all ages. They are similarly associated with polyspike and irregular slow wave activity in the EEG and severe organic cerebral disease. Clonic seizures are seen most commonly in children. Tonic seizures may present as prolonged infantile spasms but also occur in later years. Both clonic seizures and tonic seizures reveal electroencephalographic patterns of bilaterally synchronous spike and slow wave discharges. Tonic and clonic seizures, grand mal seizures, are associated with bilaterally synchronous polyspike and slow wave bursts in the interictal EEG. At the onset of a clinical seizure, the EEG first reveals increasing frequency and amplitude of cerebral activity with the formation of series of spikes; then spike and slow wave activities decrease in frequency as the seizure diminishes. Grand mal seizures may be seen at all ages, except in early infancy.

In addition to the two major classifications of partial and generalized seizures, other seizure types may occur. Erratic seizures in the newborn are tonic and/or clonic, usually unilateral yet associated with generalized paroxysmal sharp and slow waves in the EEG. Similar seizures, with or without alteration of consciousness, sometimes shift from one side to the other. These occur almost exclusively in very young children and are associated with organic disease. In the EEG, focal discharges rapidly spread over the cerebral hemisphere during the seizure, but either bilaterally synchronous or asynchronous spike and slow wave discharges are seen in the interictal record. Finally there are some seizures which cannot be classified above.

Clinical features. The distinguishing clinical characteristics of the most common forms of epilepsy can be briefly summarized. The diagnosis of a grand mal seizure (generalized, convulsive, tonic-clonic) is supported by an aura, tongue biting or incontinence during the seizure, and subsequent exhaustion, somnolence, or muscular aches, although not any of these features need be present. Petit mal epilepsy (generalized, nonconvulsive), on the other hand, is not associated with an aura or subsequent symptoms. Psychomotor seizures (partial, complex symptomatology) may be preceded by an aura of uncinate phenomena, and, although these seizures, usually automatisms, may be extremely variable from one patient to another, they tend to be stereotyped for each individual.

The incidence, etiology, and hereditary aspects of the epilepsies are discussed by Ervin (see Section 21.1). As examples of the diverse mechanisms associated with convulsive disorders, the following are of interest.

Febrile convulsions. Always generalized, febrile convulsions occur before the age of 3 years. The high familial incidence (25 per cent) and normal interictal EEG help to establish the benign nature of this condition, but 20 to 30 per cent of these children later have seizures unrelated to fever.

Post-traumatic epilepsy. These seizures occur within 4 years of the date of cerebral trauma; most often within the 1st year. The incidence of seizures following head trauma is largely dependent upon the severity of cerebral injury. Table I gives approximate statistics.

TABLE I
Incidence of Epilepsy after Head Trauma

Type of Injury	Post-traumatic Epilepsy
	%
Closed head injury	
Cerebral concussion.....	5-10
Cerebral contusion.....	25
Penetrating head injury	
No loss of consciousness or neurologic signs.....	15
Cerebral laceration.....	33
Gross cerebral defect.....	50

Myoclonus epilepsy. Myoclonus epilepsy (*Unverricht*) is a hereditary disease characterized by myoclonic lightning-like jerks of scattered muscle groups, which often fail to move the extremity and are evoked by minimal stimuli. Dementia is progressive, and signs of basal ganglia, cerebellar, and brain stem disease may occur. The disease usually begins in childhood and ends in death during early adult life. On pathological examination inclusion bodies are found in many of the neurones of the cortex and deep ganglia.

Differential diagnosis. In older children and adults the differential diagnosis of epilepsy must include syncope, severe vertigo, cataplexy-narcolepsy, and transient cerebrovascular insufficiency. Psychogenic phenomena, particularly hysteria or attacks of anxiety may be difficult and sometimes impossible to differentiate from psychomotor epilepsy.

Epileptic seizures in young children must be differentiated from several nonconvulsive phenomena. (1) Breath-holding spells occur from 6 months to 3 years of age and are provoked by crying. At the onset of crying, expiration is prolonged; the cry is held or breath is lost for about 15 seconds. Then loss of consciousness occurs for a few seconds with flaccidity, rigidity, tonic spasm, or, sometimes, a brief clonic seizure. These children often have a hypersensitive oculovagal reflex; i.e., ocular compression causes brief apnea and syncope. (2) Spasmus nutans occurs between 6 months and 2 years of age, especially in children living in a dark environment. It consists of rhythmic nodding or tremor of the head with rapid pendular nystagmus. These features can be stopped by closing the child's eyes, but forceful control of the tremor increases the nystagmus. (3) Very young girls may masturbate by squeezing their extended legs together in a tonic fashion. The child may be poorly responsive during this time and fall asleep afterwards. (4) Tics are usually more complex and less stereotyped than myoclonic jerks. The former can be voluntarily controlled for a short time. (5) Paroxysmal behavioral disturbances and temper tantrums may be very difficult to differentiate from psychomotor seizures, but the latter are more stereotyped. (6) After an unusually frightening dream, a young child may briefly appear unresponsive, but this should not be considered abnormal.

Diagnostic studies. In an attempt to determine the cause of a convulsive disorder several simple laboratory studies are advisable in addition to the EEG. The blood count, urinalysis, blood serology, fasting blood sugar, or serum calcium may be diagnostic. For example, severe anemia or leukemia, uremia, lues, hypoglycemia, and hypocalcemia may all present seizures as the initial symptom. Roentgenograms of the skull may reveal evidence of a brain tumor or other cause for convulsions.

Therapy. Most patients with convulsive seizures can be completely or adequately controlled by medication. A large number of drugs have been made available since 1938 when diphenylhydantoin (Dilantin) was introduced. The latter, administered to an adult in doses of 0.1 gm. three to four times per day, with or without phenobarbital (0.03 gm. per dose), is still

the most common treatment of grand mal or psychomotor seizures. Mesantoin (methylphenylethylhydantoin) is somewhat more potent than Dilantin in similar dosage, but more toxic. Phenylethylhydroprimidinedione (Mysoline) is at least as effective as Dilantin. The average adult dose of 0.25 gm. three to four times daily must be attained by gradual increments of smaller amounts. Trimethyloxazolidinedione (Tridione), introduced in 1945, was the first preparation effective in petit mal epilepsy. The average dose for a child is 0.3 gm. three to four times per day. Dimethylethylloxazolidinedione (Paradione) is somewhat less effective than Tridione in similar dosage. More recently ethylmethylsuccinimide (Zarontin) administered to the child in doses of 0.25 gm. three to four times daily, has been considered the drug of choice for petit mal. Other succinimides, methylphenylsuccinimide (Milonitin), 0.5 gm. three times per day, and methyl, methylphenylsuccinimide (Celontin), 0.3 gm. three to four times daily, are of benefit in petit mal; Celontin is also useful for psychomotor and grand mal seizures.

Seizure control is often attained only after trial and error. One drug should be increased from the average dosages listed above to the point of toxicity, before adding or substituting another. When discontinuing an anticonvulsant, gradual withdrawal is mandatory. In the treatment of status epilepticus, a barbiturate is the drug of choice. An intravenous dose of 300 to 500 mg. is recommended for an adult, and this dose may be repeated if necessary.

The anticonvulsant drugs are relatively safe, but many toxic reactions have been recorded. Drowsiness, dermatitis, and gastrointestinal symptoms are common to all. Depression of the bone marrow is rare but obviously serious. Certain toxic reactions are characteristic of a specific drug. Ataxia, nystagmus, gum hypertrophy, and hirsutism occur with Dilantin toxicity. Children and especially adults taking Tridione may experience photophobia. Vertigo may occur with many anticonvulsants but is most prominent with Mysoline overdosage.

Ancillary measures. There are many ancillary measures that may be appropriate in the treatment of patients with convulsive disorders. The amphetamines are useful in counteracting the drowsiness that may be a side effect of anticonvulsant medication. Some believe that amphetamine has a directly beneficial effect in petit mal epilepsy. Meprobamate (Miltown), chlordiazepoxide (Librium), and diazepam (Valium) have some anticonvulsant properties and, as tranquilizers, are preferred to the phenothiazine derivatives, for the latter tend to lower the convulsive threshold. Carbonic anhydrase inhibitors (e.g., acetazolamide) have direct anticonvulsant action, and other diuretics may be helpful, particularly for those women who experience increase in seizure frequency associated with the menstrual period. A ketogenic diet, recommended only as a last resort for children with akinetic petit mal, rarely can be maintained. Infantile spasms do not respond to any measures previously described but, for reasons still obscure, adrenocorticotrophic hormone often decreases or abolishes these seizures. Since pyridoxine deficiency in infants may cause seizures, a therapeutic trial with this vitamin is always indicated. General hygienic measures are important. People with epilepsy should avoid alcoholic beverages, overhydration, fatigue, and emotional stress.

Surgery. Surgical resection of an epileptogenic scar is of value in some patients with focal seizures, particularly temporal

lobe epilepsy. It should be considered after all conservative measures have failed. In properly selected cases, e.g., patients with a single anterior temporal lobe focus, surgery has been about 50 per cent successful in significantly decreasing the frequency or completely halting seizures. Approximately 25 per cent have shown a small decrease in seizure frequency after operation, whereas in another 25 per cent surgery has proved to be ineffective or has caused significant morbidity. The mortality rate of temporal lobectomy is only 1 to 2 per cent.

Seizures with psychic phenomena. Seizure activity evoking psychic phenomena is discussed by Ervin (see Section 21.1). These phenomena are often perceptual, characterized by illusions. An alteration in self awareness and *déjà vu* phenomena are common. Hallucinations, usually formed and complex, may be evoked by seizures. Alterations in mood or affect may occur, most often fear or depression. (Pleasurable or sexual sensations are not associated with seizures and, if laughter occurs, it is not accompanied by appropriate affect.) Disturbance of thought, especially forced thinking, may be a seizure manifestation. Automatism is the most common type of psychic phenomena associated with convulsive disorders. Automatic behavior may follow, may be part of, or may constitute the seizure itself. (The latter is, of course, psychomotor epilepsy.)

The anatomic sites of the psychical states noted above have been evaluated by surgical exploration and electrical stimulation. Although repeated stimulation at the same point in the same individual does not always evoke the same response, the following correlations have been most consistent. Illusions of an olfactory nature may be evoked from the uncus; auditory illusions, from Heschl's gyrus; illusions of taste, from the circular sulcus of the temporal lobe; and visual illusions from the posterior aspect of the temporal lobe. Stimulation of the superior lateral zones of the temporal lobe or the adjacent parietal cortex may produce hallucinations. Feelings of unreality may be evoked from the supramarginal gyrus. Other emotional phenomena may be experienced during stimulation of the temporal lobe deep in the Sylvian fissure or its under-surface. Forced thinking may occur upon stimulation of the frontal as well as the temporal lobe. The insula is associated with intestinal and other visceral symptoms. Automatism may be evoked by stimulating the circuminsular cortex, the amygdaloid nucleus, the anterior hippocampal gyrus, the hippocampus itself, the termination of the anterior commissure, or the anterior portion of the frontal lobe. Automatic activity appears to be associated with epileptic interference of connections between the midbrain-diencephalic centers and those parts of the cerebral cortex related to memory and other intellectual functions. The most common automatisms are those associated with psychomotor seizures, which usually arise in the cortex of the anterior portion of the temporal lobe but may originate in other areas of the limbic system. Sometimes small foci may trigger diencephalic (generalized) epileptogenic activity.

Psychomotor seizures often start as visceral discomfort within the abdomen or head or as emotional phenomena, e.g., anxiety. Uncinate symptoms, illusions or hallucinations of taste or smell, may occur as auras. During the seizure there is alteration of consciousness and thought processes; amnesia is invariable. The seizure may be simple and consist of a syncopal-like episode or of staring blankly into space. Autonomic features are often manifested by chewing, swallowing, or smacking of the lips. Automatic stereotyped behavior is most characteristic. The latter is often bizarre, semipurposeful, and partially or totally inappropriate, but usually the activity has some relationship to the environment. Simple automatisms may consist of fumbling with clothing, manipulation of hands, or aimless stumbling

about. More complex activities may be manifested by the pursuit of a previous line of action or habitual activity, such as boarding a bus to work. During the seizure the patient may obey simple commands; on the other hand, he may be antagonistic or assaultive.

The high incidence of interictal psychological disturbances in patients with convulsive disorders, particularly psychomotor epilepsy, has long been noted (see Section 21.1 for details). Although the neurotic or psychotic manifestations of these patients may be indistinguishable from those of nonepileptics, schizophrenic-like symptoms sometimes seen in patients with psychomotor seizures can often be differentiated from true schizophrenia. The epileptic reveals greater fluctuation of mental status and only spotty loss of associations and makes frequent attempts to maintain contact with reality; dysphasia or impaired perception may also be evident. The autisms, withdrawals, and symbolic processes seen in schizophrenia are usually absent in the patient with seizures.

Certain studies of patients with psychomotor seizures have produced evidence of the organic basis for associated behavioral and mental abnormalities. These phenomena are twice as common in the 25 per cent of patients with bitemporal lobe EEG abnormalities than in the majority who have a consistently unilateral temporal lobe focus. Moreover, in some instances amelioration of psychotic symptoms as well as seizures follows temporal lobectomy. On the other hand, suppression of seizure activity with anticonvulsant medication may, paradoxically, increase the psychological abnormalities often present in these patients.

Pain and Dizziness, the Two Most Common Neurological Symptoms

Pain. Pain, mainly a subjective phenomenon, is difficult to evaluate, but there are several factors to be considered. Threshold of pain varies greatly from one individual to another. At one end of the spectrum is the entity of congenital indifference to pain. There are no objective cerebral alterations in this condition, and it was considered a pathophysiological rather than a psychological disease. (Recent studies have revealed an absence of specific sensory end organs in the skin of these patients.) At the opposite extreme are those individuals with little tolerance for pain, and in this group psychogenic elements are predominant. Attention and distraction are the most important factors influencing the appreciation of and reaction to pain. The attenuation of response to painful stimuli by placebo therapy and the disappearance of pain with hypnosis are two well recognized examples of the power of suggestion.

The difference between "real" and "imagined" pain is more semantic than physiological. Often, however, there may be great difficulty in differentiating pain of organic or physiological origin from pain manifested as part of a psychological illness. Pain with organic disease usually is accompanied by objective signs of the disease, e.g., malignancy, ischemic phenomena, peripheral neuritis. Neuralgias, on the other hand, are not associated with organic disease, but nevertheless usually have a neurophysiological mechanism. These pains follow the anatomic course of a peripheral nerve, nerve root, or nerve plexus, and neuralgias affecting the head and face are most common. There are other

pain syndromes which do not follow specific somatic nerve distributions but are to be distinguished from pain as a manifestation of neurosis.

Cranial neuralgias. The cranial neuralgias are characterized by brief bouts of paroxysmal lancinating pain recurring within the anatomic distribution of a cranial nerve. Often the pain is triggered by external stimuli. These illnesses occur most commonly in older individuals. The pains can usually be relieved by interrupting the affected nerve. The involved nerve does not manifest objective defects on neurological examination, and neither gross nor microscopic abnormalities are seen on routine examination. Recent electron microscopic studies, however, have revealed proliferative and degenerative changes in the myelin sheaths of nerves affected by trigeminal neuralgia.

Trigeminal neuralgia. Trigeminal neuralgia is characterized by pain within the distribution of the fifth cranial nerve, predominantly the second and third divisions. Pains may be precipitated by touching the affected side of the cheek, chewing, or swallowing. This illness is often benefited by anticonvulsant medication (e.g., diphenylhydantoin), but medical therapy may not be permanent. Surgical interruption of the nerve, on the other hand, usually produces lasting relief.

Glossopharyngeal neuralgia. This condition is manifested by bouts of sharp pain in the tonsillar and aural areas, spreading to the base of the tongue and throat. The pains may be precipitated by yawning or swallowing. Superior laryngeal neuralgia is probably a fragment of glossopharyngeal neuralgia. The pain in this disease extends from the larynx to the ear, sometimes along the angle of the jaw, and is precipitated by talking or swallowing.

Geniculate neuralgia. Geniculate neuralgia is characterized by pain deep in the ear and adjacent structures. It is due to dysfunction of the geniculate (sensory) ganglion of the facial nerve.

Other craniofacial neuralgias of uncertain origin. In some cases these pains have a pathophysiological mechanism; in others the pains are of neurotic origin. One or two entities are always considered manifestations of underlying psychological disease.

Occipital neuralgia. This type of neuralgia is characterized by pain over the occipital nuchal area. The pain may extend over adjacent areas of the head and is predominantly unilateral. Pains of this nature may be due to a physiological disturbance of the occipital nerve, but psychological mechanisms must always be sought.

Temporomandibular neuralgia. This condition is manifested by pain in the temporomandibular joint, with radiation of pain beyond that area. This syndrome is due to disease or dysfunction of the temporomandibular joint, but when objective signs cannot be demonstrated by physical or roentgenographic examinations, psychogenic mechanisms are usually predominant.

Sphenopalatine neuralgia. Sphenopalatine neuralgia is characterized by pain behind the eyes, in the cheeks, in the roof of the mouth, at the root of the nose, and in the upper jaw and teeth. Sometimes this pain radiates to an ear, to the occipital nuchal area, to the shoulder or arm. Most probably, pains of this nature are psychogenic rather than due to a dysfunction of the sphenopalatine ganglia.

Atypical facial pain. Atypical facial pain is not a neuralgia as defined above. Instead, this term refers to a constant and often bizarre pain in any part of the face, head, or neck not confined to the anatomic distribution of a trigeminal or other cranial nerve. This syndrome is most common in women in

their late thirties or forties (about the time of the menopause). There is often a long past history of discomfort in the face. The pain may be completely disabling in that the symptom becomes the patient's only concern. These patients eagerly submit to unnecessary dental work and other types of surgery in an attempt to find relief. Although this disease is thought to be psychogenic, psychotherapy has not been any more beneficial than medical or surgical treatments.

Other pain syndromes which do not follow a specific peripheral nerve distribution and may be confused with pain of psychological origin are related to diseases or dysfunctions of the autonomic nervous system or the central nervous system.

Pain originating in the autonomic nervous system

Causalgia. Causalgia is due to dysfunction of sympathetic nerve fibers usually associated with partial peripheral nerve injury. It is characterized by a peculiar burning hyperpathia affecting a poorly demarcated zone of a hand or foot. Associated autonomic and trophic changes in the affected part consist of smoothened and reddened skin, excessive perspiration, swelling, and tapered digits. Sympathectomy is usually beneficial.

Reflex dystrophies. There are other reflex (sympathetic) dystrophies that follow minor trauma. They cause not only pain but also muscle contracture and atrophy (with paralysis or weakness), vasomotor changes (hypothermia, cyanosis, edema), and trophic changes of bones, skin, hair, or nails. Sudeck's atrophy, i.e., post-traumatic osteoporosis, is considered in this category.

Shoulder-hand syndrome. The shoulder-hand syndrome is a form of reflex sympathetic dystrophy but of nontraumatic origin. It is usually associated with coronary heart disease, although it may be seen with diseases of other viscera. This condition is manifested by pain and restricted mobility of the affected extremity. Trophic and vasomotor changes take place in the skin, muscles, bones, and joints. The shoulder-hand syndrome can be prevented by activation of the extremity; physical therapy is required once the symptoms have begun.

Pain originating in the central nervous system

Thalamic syndrome. The thalamic syndrome is characterized by continuous, often indescribable, pain or discomfort over one part or one side of the body. The threshold to superficial pain is slightly raised, but when the stimulus is appreciated it is unusually painful or disagreeable, and the zone of pain may spread from the area of the stimulus over ever widening adjacent zones. There may be delay in appreciation of the stimulus, and the resultant sensation may persist for an unusually long period of time. The thalamic syndrome is usually due to infarction of the contralateral thalamus after occlusion of the thalamogeniculate branch of the posterior cerebral artery. Many characteristics of the thalamic syndrome may occur in other lesions affecting sensory pathways within the central nervous system. Pain of central nervous system origin is extremely resistant to all forms of medical, surgical, and psychiatric treatment. Tranquilizing medications, such as the phenothiazines in high dosage, afford more relief than analgesics. Stereotactic surgery has been used with varying success.

Phantom limb pain. Pain of a phantom limb is a poorly understood, complex, psychophysiological phenomenon. Awareness of a phantom limb is common after amputation. In a small number of patients (2 to 5 per cent) the phantom may

TABLE II

Differentiation of Dizziness of Labyrinthine Origin from That of Central Nervous System Origin

Labyrinthine Disease	Central Nervous System Disease
There may be history of past bouts of dizziness or ear disease.	There may be history of central nervous system disease, e.g., old symptoms of multiple sclerosis.
Episodes of dizziness are paroxysmal.	Dizziness is less acute and more prolonged.
Dizziness is precipitated or aggravated by movement of the head even while lying in bed.	Dizziness need not be aggravated by head movement. Dizziness due to vertebrobasilar artery insufficiency may be precipitated by arising from the horizontal position or by neck movement.
There may be associated symptoms or signs of hearing impairment or tinnitus. Nausea and vomiting often accompany dizziness.	There often are associated symptoms or signs of disease implicating the brain stem, such as diplopia or sensory or motor signs.
Nystagmus, when present during an attack, is horizontal.	Nystagmus may be vertical or rotatory as well as horizontal and is often present after dizziness has disappeared.
Ataxia, if present, occurs only during the attack.	Ataxia may be present without dizziness.
Tests	Tests
The caloric test may be normal or reveal increased or decreased reactivity of the labyrinth.	The caloric response is usually normal but may evoke nystagmus of perverted or incongruent type. ^a
Audiometry often reveals defective acuity and, in Ménière's syndrome, recruitment of loudness of pure tones but impaired intelligibility of amplified speech.	Audiometry is usually normal. ^b
Roentgenograms of the skull may reveal evidence of old mastoiditis or cholesteatoma.	Roentgenograms may reveal intracranial pathology. ^c
Other laboratory features are usually normal.	The EEG, spinal fluid, angiography, or pneumoencephalography may reveal abnormality. ^d

^a Absent caloric response on the side of an acoustic neuroma.

^b Nerve deafness with acoustic neuroma.

^c Enlarged acoustic meatus caused by acoustic neuroma.

^d Elevated cerebrospinal fluid protein with acoustic neuroma.

not disappear or may become painful. The pain appears to be initiated at the amputation stump and perpetuated in sensory cerebral centers.

Epilepsy. Pain as an epileptic manifestation may occur but is rare (see above).

Pains of poorly understood mechanism

Acroparesthesias. These are unpleasant, crawling, tingling, sometimes painful sensations, usually in the hands and arms. These symptoms occur predominantly at rest or at night and are diminished by rubbing or moving the extremities. (The restless legs syndrome (see Section 10.1) is probably related to this condition.)

Postherpetic neuralgia. This condition may persist for a long period of time after the initial infection of herpes zoster. It is not benefited by surgical section of the affected nerve.

Post-traumatic neck pain. Pain in neck musculature often persists for many months after head and neck injury (whiplash effect). Demonstrable changes are not evident in these muscles.

Visceral pain. Pain of visceral origin or pain referred from distant sites may be extremely difficult to diagnose and differentiate from psychogenic pain.

Headache. See Section 30.14.

Dizziness. The symptom of "dizziness" has different meanings for different people. Unfortunately, individuals not only use the words "dizziness" and "vertigo" interchangeably, but they also use the term "dizziness" as synonymous with feelings of faintness, malaise, or headache. *Dizziness* is a sense of imbalance or unsteadiness, whereas *vertigo* is a form of dizziness characterized by a spinning sensation. Although it is customary to attempt to distinguish vertigo from less specific forms of dizziness, in the author's opinion, this differentiation is not crucial. Dizziness or vertigo may or may not be present with labyrinthine disease or disease of the nervous system. Localization of disease cannot be made on the basis of a single symptom. More important is the differentiation of dizziness of labyrinthine (peripheral) origin from dizziness of central nervous system origin by the criteria listed in Table II.

Differential diagnosis

Diseases of the ear. Dizziness may be caused by obstructions in the external or middle chambers of the ear. The most common lesions are wax or foreign body in the external canal, block of the Eustachian tube, or disease of the middle ear, particularly inflammation or injury.

Diseases of the internal ear are the most common causes of dizziness.

Labyrinthitis is due to injury or irritation of the labyrinth by infection, allergy, vascular disease, trauma, or tumor (cholesteatoma). Drugs and toxins often associated with labyrinthitis include streptomycin, quinidine, salicylates, anticonvulsants, nicotine, and carbon monoxide. Many dysfunctions of the labyrinth associated with position and movement are of indeterminate mechanism. Labyrinthitis is characterized by episodes of dizziness which may recur in series. The disease is not progressive.

Ménière's syndrome is caused by hydrops, less commonly hemorrhage, of the labyrinth. The pathogenesis of this syndrome is unknown, but many of the etiological factors listed under labyrinthitis also may be operative here. This condition is clinically distinguished from labyrinthitis by the additional symptoms of tinnitus and hearing loss. The latter are often

most marked during acute bouts of dizziness but persist intermittently or continuously thereafter and often grow progressively severe. There is impaired intelligibility of amplified speech, and audiometry reveals recruitment phenomena.

Diseases of the eighth cranial nerve or brain stem. The auditory nerve may be affected by meningitis, trauma, or, most often, tumor (acoustic neuroma). In the brain stem, involvement of the vestibular nuclei is particularly associated with dizziness, but lesions in other areas of the brain stem also cause this symptom. All etiological categories must be considered. Vascular diseases (vertebrobasilar insufficiency and the lateral medullary syndrome) are predominant in the elderly. Degenerative diseases such as multiple sclerosis and syringobulbia are to be considered in the younger age group. Inflammation, trauma, or intrinsic tumor are less common causes of brain stem disease.

Diseases of the cerebellum or cerebrum. The symptom of "dizziness" with lesions of the brain is often likely to be "faintness" or "lightheadedness" poorly described. Any anatomic or metabolic disease of the cerebrum or cerebellum, especially of an acute nature, may cause dizziness. The toxic effect of alcohol is the most common example. Vascular diseases, post-traumatic conditions, and cerebellar tumors are more frequent causes of dizziness than deficiency states or inflammatory diseases.

Physiological dysfunctions. Dizziness sometimes occurs prior to syncope. Vertigo may be associated with and, in rare instances, is the only manifestation of epilepsy. Dizziness occasionally accompanies migraine. After headache, dizziness is the most common symptom of the postconcussion syndrome.

Proprioceptive impairment. Imbalance due to position sense defects may be interpreted by the patient as dizziness. Diseases affecting the posterior columns of the spinal cord and peripheral neuropathies are the major considerations.

Diseases of the eye. Intrinsic eye muscle imbalance or extraocular muscle paresis sometimes causes dizziness. Refractive error and glaucoma may be associated with this symptom.

Systemic diseases. Virtually any generalized illness may cause dizziness. Endocrine disturbances are sometimes associated with dizziness; particularly hypocalcemia, hypoglycemia, hypothyroidism, and hypo- or hyperadrenalism. Systemic infections, hematological diseases, deficiency states (especially pellagra), and allergic and toxic phenomena often present dizziness as a prominent symptom.

Mental and Emotional Syndromes

Unconsciousness. The definition of coma is not precise, for there is no sharp distinction between stupor, semicoma, and coma. As a rule of thumb, stuporous individuals respond to verbal as well as noxious stimuli, while semicomatose patients respond only to superficial and deep pain stimuli; patients in coma respond only to deep stimuli or do not respond at all.

Syncope. Syncope is a brief loss of consciousness, less than 1 minute, and usually no more than 15 seconds, in duration.

Differential diagnosis of syncope

I. Primary cerebral mechanisms

A. Vascular disease

1. Cerebral ischemia (thrombosis, hemorrhage or embolism)
2. Subarachnoid hemorrhage
3. Hypertensive encephalopathy
4. Carotid sinus reflex (direct cerebral effect)
5. Migraine

B. Epilepsy

C. Other cerebral disease or dysfunction

1. Cerebral concussion

2. Severe vertigo

D. Psychological disease

II. Cardiovascular factors

A. Heart block

1. Adams-Stokes syndrome
2. Carotid sinus effect (vasovagal)
3. Other vagal reflexes
 - a. Vagovagal (precipitated by defects in swallowing)
 - b. Oculovagal (precipitated by pressure over the eyeball)
 - c. Pulmonary or abdominal vagal (precipitated by lung or gastrointestinal disease)

B. Decreased stroke volume of heart

1. Aortic stenosis
2. Other valvular disease (mitral insufficiency or stenosis)
3. Cardiac arrhythmias and severe tachycardia
4. Myocardial infarction and other heart disease

C. Hypotension

1. Orthostatic hypotension (convalescence, drug therapy, postsympathectomy, pregnancy, exhaustion, malnutrition, prolonged standing, adrenal insufficiency, diabetes mellitus)
2. Carotid sinus and other vasovagal reflexes of a vasodepressor nature
3. Shock of any cause (e.g., dissecting aneurysm of the aorta)
4. Micturition syncope (mechanism of the latter not definitely established as hypotension)
5. Severe pain
6. Emotional stimuli

III. Pulmonary causes

- A. Hyperventilation
- B. Cough or the Valsalva maneuver
- C. Pulmonary embolism
- D. Positive pressure breathing
- E. Pulmonary hypertension

IV. Changes in blood: oxygen, carbon dioxide, glucose

- A. Hypoxia (e.g., high altitude or asphyxia)
- B. Hypocapnea or hypercapnea
- C. Hypoglycemia
- D. Other metabolic disturbances

V. Other forms of severe stress (see the differential diagnosis of coma)

Coma. Coma of acute onset is most likely due to trauma, cerebrovascular or cardiovascular disease, intoxication (especially alcoholism), heat stroke, or allergic reactions. Gradually developing coma is probably due to meningoencephalitis or other infectious processes, cerebral neoplasms, metabolic diseases, anoxia, or anemic phenomena. A history often is not available, and the general physical and neurological examinations may not establish the cause of coma. Laboratory studies should then include a blood count and urinalysis (the hematocrit and urinary sugar and acetone can be determined quickly); roentgenograms of the skull; a spinal tap; an EEG; and an evaluation of the blood, vomitus, or urine for drug levels.

Management. In the management of the unconscious patient, the immediate primary concern is maintenance of vital functions (blood pressure, pulse, temperature, and respiration). Shock is the most common cardiovascular factor requiring treatment. Tachycardia or bradycardia may be more difficult to correct. High fever must be brought down by ice packs. Alter-

ations in rate and depth of respirations or evidence of an obstructed air passage may require correction by means of tracheostomy and artificial respiration. Metabolic factors cannot be immediately evaluated, but a major concern is hypoglycemia. Blood should be drawn for analysis, and then 50 cc. of 20 per cent glucose should be intravenously administered. Nutrition, hydration, and electrolyte balance must be maintained. Attention to the bladder and bowels is necessary, and a retention catheter is usually required. The patient should be turned frequently to prevent pneumonia. Sedatives are to be avoided, but if extreme restlessness occurs the drug of choice is paraldehyde.

Differential diagnosis of coma

- I. Primarily intracranial
 - A. Trauma: concussion, contusion, laceration; subdural or epidural hemorrhage
 - B. Vascular disease: thrombosis, hemorrhage, embolism; subarachnoid hemorrhage
 - C. Inflammatory disease: meningitis, encephalitis, abscess
 - D. Neoplastic disease: primary or metastatic
 - E. Convulsive disorders
 - F. Increased intracranial pressure
 - G. Neurosis or psychosis: mutism, extreme negativism, hysteria, depression, catatonic schizophrenia (in these conditions the "coma" more apparent than real)
- II. Primarily extracranial
 - A. Cardiovascular disease: shock, hemorrhage, hypotension, hypertensive encephalopathy; myocardial infarction, heart failure
 - B. Pulmonary disease: hypoxia or asphyxia; pneumonia, pulmonary embolism
 - C. Metabolic or toxic diseases
 1. Endogenous toxins
 - a. Uremia
 - b. Diabetic acidosis or hypoglycemia
 - c. Eclampsia
 - d. Hepatic coma
 - e. Adrenal insufficiency
 - f. Other endocrine or electrolyte disorders (e.g., heat stroke)
 2. Exogenous toxins
 - a. Alcohol
 - b. Sedatives, analgesics, narcotics
 - c. Other drugs: tranquilizers, anticonvulsants
 - d. Heavy metal poisons
 - e. Other poisons: organic compounds (e.g., carbon tetrachloride), carbon monoxide
 - D. Any form of severe stress
 1. Severe disease
 2. Hyperthermia or hypothermia
 3. Allergic reactions
 4. Electric shock

Delirium. Delirium, in the opinion of this author, is a transient state of restlessness or excitement, accompanied by impairment of mental function. All intellectual spheres are affected, particularly orientation for time. Fear may be prominent, with tendency to fight as in a panic. Visual hallucinations and illusions or delusions are common. There is often increased suggestibility, heightened response to stimuli, and emotional lability. Confabulation is common, but

speech may be incoherent. Symptoms fluctuate markedly and tend to be most severe at night. Delirium may last hours or days, sometimes as long as a month.

Almost any organic brain disease may cause delirium. Most common are intoxications, either endogenous or exogenous (especially alcohol or drugs). Cerebral trauma, febrile illnesses, metabolic or other systemic diseases, deficiency and exhaustive states are frequent etiological factors. Patients with senile cerebral disease are particularly predisposed to the development of delirium. Certain clinical manifestations of delirium may be clues to the cause of the toxic state. The classical delirium tremens, especially when associated with Korsakoff's psychosis, leaves little doubt about the diagnosis of chronic alcoholic intoxication. If depression of consciousness follows delirium, the toxic effects of sedatives, hypnotics, or narcotics must be suspected. Amphetamine intoxication often produces euphoria preceding delirium. The toxic effects of alkaloids of the belladonna group are manifested by parasympathomimetic reactions and sometimes choreiform movements. The phenothiazine derivatives and other tranquilizers may cause dyskinesias with delirium as manifestations of toxicity. Cocaine intoxication results in extreme excitement. In addition to excitement, hallucinations and illusions are particularly prominent with marijuana, mescaline and lysergic acid diethylamide (LSD) toxicity.

Although usually a manifestation of organic brain disease, the features of delirium, except for impaired intellectual function, may be psychogenic. Symptoms of delirium may occur in a patient with manic depressive or schizophrenic psychoses, but more often the patient is hysterical and Ganser's syndrome may be concomitant.

Management. In managing a delirious patient, force must be avoided. Movement of the patient by gentle means usually can be accomplished. For example, several people gathering around the patient can gradually crowd him into his room. The latter should be quiet, but lit and bare of decoration. Someone should always be in attendance to calm and reassure the patient. Restraints should be avoided and sedation used sparingly. Paraldehyde is the drug of choice, 10 to 20 cc. in iced fruit juice, or a similar amount in olive oil per rectum; if necessary, 3 to 5 cc. may be injected deep into the muscles of each buttock. Intramuscular chlorpromazine (Thorazine, 50 to 400 mg.) may be administered every 4 hours if necessary. Hydration must be maintained, with vitamin supplementation. Oral or intravenous administration is preferred to the nasogastric tube because of the hyperactivity that the latter often evokes.

Hysteria. The hysterical patient usually appears bland and indifferent to his defect. On the other hand, some patients are anxious, or their attitude is evocative of sympathy. The marked suggestibility of the patient with hysteria is manifested by contradictory responses and changes in and disproportion between symptoms and signs. The history of an emotional disturbance that has acted as a precipitating factor or a past history of psychosomatic phenomena often can be elicited. In differentiating hysteria from malingering, one notes less tangible evidence of secondary gain in the former. For example, the symptoms may allow the hysterical patient escape from

responsibility, whereas the malingerer may seek the settlement of a law suit. The signs of hysteria discussed below usually can be applied to malingering.

Sensory. Psychogenic sensory phenomena are commonly manifested by analgesia; total analgesia is rare as an organic phenomenon. On the other hand, extreme hypersensitivity to examination may be found in hysterical individuals, and responses may not vary with the intensity of the stimulus. A psychogenic glove or stocking distribution of sensory loss has a sharp border, but hypalgesia and hypesthesia, found in a similar distribution with peripheral neuropathy, have a less distinct border and gradations of increasing sensitivity in the distal to proximal direction. The sensory impairment in hysteria does not conform to the anatomical zone of a peripheral nerve or dermatome, and in an extremity the defect may extend only over the medial or lateral side. Inconsistencies in sensory responses are frequently noted. Thus, the patient may profess loss of superficial sensation and yet be able to identify objects placed in his hand. He may deny superficial abdominal sensation and yet abdominal reflexes can be elicited. Complete loss of position sense may seem to be present upon direct testing and yet the patient is well able to use the extremity with eyes closed. Autonomic changes normally associated with pain are useful in testing the patient with hysteria. The involuntary responses of tachycardia, hypertension, hyperpnea, and mydriasis may be evoked even though the patient claims to be insensitive to the painful stimulus. There are several "tricks" used to foil the malingerer and detect the hysteric. A dull individual may be asked to say "yes" when he feels the pin prick and "no" when he does not. With the patient's hands crossed behind his back and fingers interlaced, quickly testing the sensation of right and left fingers may evoke inconsistent responses. The patient with a hemisensory impairment often orients the defective side to his environment, e.g., the wall next to the examining table. As a result, the hysteric may reveal a hemisensory defect on one side when supine and on the opposite side when prone. Over the trunk, the change from normal to impaired sensation is usually in the exact midline with a nonorganic hemisensory defect, in contrast to the overlap beyond the midline of normal sensation with a hemisensory lesion of organic origin. Vibration sensation in hysteria may be experienced differently over the right and left halves of the same bone, such as the sternum or skull. A hemisensory defect that includes the penis, vagina, or rectum is very rarely of organic origin.

Motor. Psychogenic weakness usually varies with the effort of the examiner testing the strength of the affected part. The patient may contract antagonist muscles in an attempt to simulate weakness of protagonist muscles, and resistance of "weak" muscles to passive movement is sometimes found. Covert observation of the patient may reveal withdrawal to unexpected pain stimuli or other use of "paralytic" muscles as when dressing. Inconsistencies may be found in the patient's responses when he is asked to move those fingers that are touched while his hands are crossed behind his back with fingers interlaced. In hysterical hemiplegia, the face and tongue muscles are spared and a circumducting gait is not evident. Hoover's sign is present when downward movement of the hysterically paralyzed leg occurs while the patient lifts his normal leg. Downward drift of an hysterically weak upper extremity is not associated with pronation of organic weakness. There may be lack of resistance on testing dorsiflexors of the feet, and yet the patient may be able to walk on his heels. In psychogenic paraplegia, the urinary and rectal sphincters are usually unaffected.

Coordination. Defects of coordination seen in hysteria are often gross and bizarre. In spite of marked ataxia on finger-to-nose and heel-to-knee tests, the patient may be able to perform fine movements normally. During the Romberg test, the patient may sway only from the hips or fall *en masse* without attempting to catch himself; distracting the patient

during the test sometimes prevents him from falling. Associated movements are often normal in these patients, e.g., normal swing of the "paralyzed" arm while walking.

Reflexes. Reflexes are usually normal in patients with hysteria, but absent gag reflexes and decreased corneal reflexes may occur. Symmetry of diminished or absent reflexes lessens the likelihood of organic disease.

Special senses. With the exception of vision, the special senses usually are not impaired on an hysterical basis. Occasionally, hearing loss is psychogenic and then is usually bilateral and complete; such a patient will make no attempt to read lips. Rarely is the loss of sense of taste or smell hysterical; these defects are very difficult to differentiate from organic lesions. Psychogenic blindness is usually bilateral. When asked to look at a close object, convergence occurs in the organically blind but not in the hysteric. Hysterical amblyopia is often associated with tubular constriction of visual fields. Cortical blindness may simulate psychogenic blindness in that normal pupillary reactions and optic fundi are seen in both conditions. Similarly, the normal funduscopic examination of patients whose blindness is due to retrolbulbar neuritis may lead to the erroneous diagnosis of hysteria.

Other modalities. A large variety of other symptoms may be psychogenic. Dysphonia is the most common speech disorder of this nature. Dysphagia, globus hystericus, may accompany the latter or occur independently. Respiratory dysfunctions, particularly hyperventilation, are often hysterical. Urinary retention frequently has a psychological mechanism, urinary incontinence rarely so. Tics and habit spasms are readily classified as psychogenic. Fits or fainting of a hysterical nature, on the other hand, may be very difficult to differentiate from psychomotor epilepsy or syncope.

Memory. Amnesia is often of hysterical or psychological origin, and its differentiation from memory loss of organic disease may be difficult. Amnesia due to an organic lesion is frequently abrupt and (when associated with trauma) retrograde, whereas the memory loss of psychological origin is often of vague onset and termination. Recovery from organic amnesia is usually incomplete and followed by confusion for hours or days; there is no recall of events during the illness. After the hysterical patient has recovered memory, complete return to normal mentation occurs and he may remember isolated events during the past period of amnesia. In organic disease, precipitating factors may be obvious (e.g., trauma), or occult (e.g., amnesia as the only symptom of a cerebrovascular lesion). A "traumatic" emotional experience may precipitate hysterical amnesia, which serves a psychological need. The behavior of a patient with organic loss of memory is often abnormal, and delirium is common. On the other hand, the behavior of a patient with psychogenic amnesia is frequently purposeful, and he is usually in excellent contact with his surroundings. Amnesia of organic disease is most often generalized in that it affects all intellectual spheres, whereas in hysteria there may be selective loss of certain psychologically stressful topics. Organic amnesia is frequently accompanied by objective neurological signs; psychogenic memory loss, by hysterical signs.

Special tests. Special tests may be of aid in making the diagnosis of hysteria. The EEG (see Section 10.1) in patients with hysterical blindness usually reveals normal suppression of

α -rhythm when the eyes are opened and a driving response to photic stimulation. Under sodium Amytal, psychogenic signs tend to disappear or diminish whereas organic signs are exaggerated. Psychometric tests and hypnosis are useful in evaluating the hysterical patient.

Denial of illness or anosognosia. In this state the patient either denies his physical defect, or there is lost or impaired perception or conception of the affected part. The patient may deny the existence of the affected part of the body or may experience a feeling of depersonalization toward the affected part. Any type of defect may be denied, usually weakness (hemiparesis), or blindness.

There are many degrees of denial of illness. Anosognosia may be explicit, with associated confabulation, or it may be implicit and manifested by withdrawal, inattention, or other psychological mechanisms. Denial may assume various forms of disturbed orientation. For example, autotopagnosia is a disorientation of body parts or defect in body schema, and finger agnosia of the Gerstmann syndrome is one of its manifestations. Reduplication of parts of the body or place or time may occur. Paraphasia (the substitution of a partially incorrect term for the proper word) is common. The individual may refer to himself in the third person.

Anosognosia is most often associated with lesions of the nondominant hemisphere and resultant left hemiparesis, but it may occur with lesions in any part of the brain. The site of brain damage determines the disability that is denied and the perceptual symbolic structure or language in which the denial is expressed. The mechanism of denial, on the other hand, is much more complex. It includes the integration of environmental factors, past experiences, premorbid personality, symbolic values, and type of disability, as well as the degree of brain damage or dysfunction.

Organic mental syndrome in adults

Progressive manifestations. The first sign of organic mental disease is a reduction in adaptive function. There is decreasing interest in social activities. The individual becomes less emotionally stable. Mental processes are slower, and physical activity is also diminished. With the patient's awareness of these changes, depression and anxiety may occur. Sedatives and alcoholic beverages may cause unusually marked lethargy. As all of the above factors increase, the patient becomes more self-absorbed and less sensitive to others. There is further slowing of thought, speech and movement. Memory for recent events becomes slightly impaired, the patient finds it difficult to deal with abstract concepts, and judgment is defective.

Further deterioration is manifested by loss of inhibition. Dress becomes less orderly. Behavior and language are irrelevant, facetious, or circumstantial. Affect is flattened or emotional lability is prominent. All intellectual factors are further impaired with particular difficulty in calculation and in orientation for time. Premorbid personality factors often become prominent, and psychotic behavior may then occur. Lethargy and inappropriate sleep alternate with restlessness. The patient no longer recognizes his deficiencies, and anxiety of the past is lost. Sedatives, tranquilizing medication, alcoholic beverages, intercurrent illnesses, or change in environment (such as hospitalization) exacerbate mental symptoms and may provoke delirium.

The individual at the next stage has obvious dementia. Nevertheless, vocabulary and past memory may still be ade-

quate, and these factors help to differentiate recent organic mental syndromes from congenital or educational defects. Disorientation in all spheres is evident, with severe impairment of all intellectual functions. Confabulation or perseveration of speech and activity occur. Passivity or catatonic posturing may be noted; on the other hand, hyperactivity often is present. The patient becomes relatively indifferent to noxious stimuli but sometimes these evoke excessive infantile responses of crying or rage.

Finally, the patient is totally incapable of caring for himself. He is incontinent of urine and feces and unable to walk or talk. The patient is seemingly unaware of visual, auditory, or noxious stimuli. If he reacts to the latter, it is a generalized rather than a focal reaction. Terminally, the patient becomes stuporous and lapses into coma.

Brain damage or dysfunction of childhood. The extent of neurological disability is dependent upon the size, location, activity, focal or diffuse nature, and age of onset of the cerebral lesion. Age is a particularly important variable. Brain injury in the prenatal or neonatal period may cause severe and permanent damage, whereas similar injury in an older child may be tolerated to a marked degree with much greater recuperation.

Mental retardation. Mental retardation is a general term that includes all forms of intellectual impairment, with onset at birth or early age. The degree may range from idiots, or those humans who barely survive on an almost vegetative level, to the children who have difficulty in school but lead a normal life and will be able to carry out customary social functions and perform simple work. Many neurological features may be associated with intellectual impairment. Most common is speech retardation and subsequent speech disturbance, particularly indistinct speech. In addition, neuromuscular development is often retarded. Obvious motor defects as paresis, dyskinesia, or ataxia may be present. In such patients, cerebral palsy and mental retardation coexist, but it must be emphasized that the two often occur independently. Sensory function is sometimes impaired, and defects of hearing or vision are not uncommon. Other abnormal signs may be noted in the neurological examination. Visceral defects or dysfunctions may be manifested by unusual susceptibility to upper respiratory tract infections or infantile feeding problems. Defective regulation of vital signs is often revealed by excessive responses of temperature, pulse, or respiration to relatively minimal stress. Convulsive seizures are common in the mentally retarded. Emotional symptoms are almost invariable and related to the type and extent of the cerebral lesion, as well as to environmental stresses. Those patients with lesser degrees of retardation are more capable of appreciating failure, feeling rejection, and experiencing frustration and insecurity.

Infancy. Difficulty in making the diagnosis of mental retardation is inversely proportional to the age of the patient. The diagnosis may be impossible in the newborn unless there are obvious signs of cerebral disease. Neonatal infants who are comatose, or have bulging fontanels indicative of increased intracranial pressure, or are in the opisthotonic position with dilated fixed pupils, almost always have some residual cerebral defect, if they survive. In other newborns, abnormal signs are only suggestive of brain damage. The most common of these signs are an abnormal cry, altered autonomic function, cranial nerve palsies, and motor abnormalities. The last may be manifested by myoclonus; defects in posture or movement; or asymmetry of motor power, tone, or reflexes. Analgesia or anesthesia is sometimes noted. Lack of blinking, sucking, grasping, or Moro reflex in the newborn are all very suggestive of cerebral disease.

Minimal brain dysfunction. The term "minimal

brain dysfunction" is preferred to "slight brain damage," for the latter falsely connotes a poor prognosis. In point of fact, organic disease in these children may be transient, insignificant, or absent. The category of minimal brain dysfunction includes those children of normal intelligence (or those just below or above average intelligence) with behavioral and/or learning disabilities. Neurological defects or evidence of socioeconomic or emotional deprivation are not present or are too slight to be obvious.

Behavioral alterations. Behavioral alterations are usually manifested as deviations in motor activity and interrelated defects in attention. Hyperactivity is the most common characteristic of minimal brain dysfunction. The child is constantly active and shows lack of inhibition and impulse control. He touches everything and speaks and acts impulsively; and his behavior is in other ways disruptive, inappropriate, or antisocial. Emotional lability is often present. The child cries with minimal provocation; temper tantrums and panic are easily evoked. Paradoxical increase in activity with administration of phenobarbital and amelioration of hyperactivity after the administration of amphetamine are often noted. In a small percentage of cases, decrease in physical activity may be a manifestation of minimal brain dysfunction.

Attention defects. Most children with this condition have difficulty in focusing and sustaining their attention, for they are distracted by everything. As in the immature, they cannot discriminate unimportant from important stimuli in the environment. The degree of impairment of attention changes from time to time, causing the uninformed observer to suspect psychological mechanisms. Defective attention impairs the ability to deal with abstract concepts and interferes with the learning process. In a smaller percentage of children with minimal brain dysfunction, a phenomenon opposite to the above is present; these children are preoccupied with detail. They show markedly decreased response to different stimuli; perseveration of speech or actions may be noted.

Learning disabilities. Learning disabilities, either generalized or specific, are common in patients with minimal brain dysfunction. Perceptual motor deficits often occur. The child may be poor in writing, drawing, and, particularly, copying geometric figures. Concept formation is frequently disturbed. Specific learning deficits may be present in only one sphere such as reading, spelling, or calculation. Scatter of performance within individual psychometric tests and differences from one test to another are often seen.

Neurological signs. There often are equivocal or minimal ("soft") neurological signs. Defects in coordination may be manifested by a generalized awkwardness (maladroitness), poor finger coordination, or dysdiadochokinesis. Speech defects or a history of retarded speech development may be noted. Confusion of right and left often occurs. Sometimes transient strabismus is seen. Mild somatic sensory defects may be present or slight impairment of hearing or vision. Occasionally, physical defects are evident.

History. The history is of some value in establishing the diagnosis of minimal brain dysfunction. Sometimes slightly abnormal factors in the prenatal, perinatal, or neonatal history can be elicited. Defects in the developmental history or abnormal socioeconomic factors occasionally are noted. Impaired academic progress is most common. There is often a history of similar symptoms in a parent or sibling. Minimal brain dysfunction occurs more commonly in males than females.

Laboratory studies. Laboratory studies are of relatively little value. The EEG may be abnormal or borderline abnormal. Fourteen and 6 per second positive spikes are sometimes associated with minimal brain dysfunction, and many other slight EEG abnormalities have been noted. Psychometric studies are valuable but require expert interpretation.

Diagnosis. Obviously, the diagnosis of minimal brain dysfunction is particularly difficult to establish during the first few years of life, but there may be many clues.

During the 1st month of life, difficulty in sucking or other feeding problems, alteration in expected muscle tone, cranky behavior, or unusual docility may be evidence of brain dysfunction.

At 9 months of age, better criteria exist for the diagnosis of minimal brain dysfunction. The degree of cerebral defect roughly corresponds to the quality and quantity of abnormal signs. In the motor sphere, alteration of muscle tone; abnormal posture of the extremities, trunk, head, or neck; or altered use of an arm or hand are usually significant (see Section 10.1). Eye signs of strabismus, nystagmus, or failure to fixate may be meaningful. Other neurological signs of importance are reflex alteration or persistence of the tonic neck reflex. Retardation in adaptive and social factors is often significant.

In the preschool years, minimal brain dysfunction may be indicated by delay in walking, speaking, or toilet-training. Impaired coordination and other failures to attain expected landmarks of development are important signs. Simplicity of play, choice of younger playmates, and lack of imagination are further clues to this disorder.

Differential diagnosis of organic brain disease of children

Deprivation. Deprivation may cause reversible symptoms and signs of organic brain disease. Malnutrition, avitaminosis, and anemia are well recognized examples of this fact. Emotional deprivation, as occurs with absence of a mother or mother figure or lack of affection, often results in a retarded child. The deprivation of social stimuli, contact with other human beings, may similarly cause mental retardation. Early correction of these factors leads to a normal course.

Autism. An autistic infant is unable to make contact with his environment. There is resultant extreme aloofness. The child does not respond to external stimuli; e.g., when picked up and cradled he does not cuddle or adapt himself to the other individual. There is often obsessive insistence on sameness and corresponding aversion to new things. This marked inflexibility of personality may be strongly defended by temper tantrums or rages. The onset of walking and especially speaking is delayed. (The mechanism of this condition is probably due to an inherent constitutional defect. Some have implicated emotional factors, for mothers of these children have been described as distant and emotionally cool. These maternal attitudes, on the other hand, may well be the mother's reaction to the unloving child, for love must be reciprocated to endure.)

Schizophrenia. Childhood schizophrenia may be first manifested as autism; the diagnosis of schizophrenia is being made as early as the 3rd and 4th year of life. The schizophrenic child, in concert with the autistic child, does not respond to the environment, other children, or adults. Sometimes activity is diminished, but more often hyperactive behavior is noted. Repetitive movements such as rocking and swinging are common. Speech may be retarded or develop in bursts. Regression (in contrast to retardation) of mental and physical development occasionally occurs.

Communication defects. Speech retardation is sometimes the result of overindulgence; the child finds that verbal communication is not required, for his needs are anticipated and immediately fulfilled. Deafness as a cause of speech retardation and associated behavioral impairment always must be considered. Unrecognized visual impairment may retard mental development.

Physiological defects. Hysteria and other psychogenic phenomena are occasionally misinterpreted as physical or mental retardation. The postictal state is associated with a dulling of mentation, and frequent seizures often prolong this condition. During petit mal status epilepticus, the patient may appear awake with marked impairment of intellectual functions. Prolonged systemic illnesses in children are frequently associated with mental retardation. Some children, more often those who

are left-handed than right-handed, have reading and writing difficulties because of maturational dysfunction in the correlation of auditory, visual, and speech mechanisms; mirror writing may be prominent, and reading difficulty may be related to similar transposition of images.

ASSESSMENT IN PSYCHIATRY

Diagnosis may be defined as the description of signs and symptoms of disordered functions and their classification into entities that are associated with a predictable outcome.

However, because the etiology of many medical disorders has been clarified and specific therapies are available, a medical diagnosis also often permits inferences concerning the etiology of a disorder, as well as the choice of a specific treatment procedure.

In the main, psychiatry has also followed the medical tradition according to which diagnosis and assessment govern the initial phases of the doctor-patient encounter. On the other hand, the role of diagnosis in psychiatry is not quite analogous to its place in other fields of medicine, since, in contrast to the medical disorders, the etiology of many of the psychiatric syndromes is not yet fully understood, and treatment is often empirical. Thus, formal diagnosis in psychiatry does not always implicate specific etiological factors, nor does it always facilitate treatment decisions. To illustrate, under our present nosological system, psychiatric disorders which belong to diverse diagnostic categories are considered amenable to similar treatment procedures. The same treatment method—psychotherapy—is often employed for such conditions as conversion reaction, depression, psychophysiological disorder, and sexual deviation, which differ widely with respect to their clinical features. In these cases, consequently, a formal diagnosis per se is of limited value in planning treatment.

Despite these limitations, accurate assessment does play an important role in psychiatry. Clinical experience has shown that, on the basis of such assessment, it is possible, with respect to certain diagnostic entities, to predict the patient's response to therapy with a fair degree of accuracy. For example, the acute symptoms of many schizophrenic patients improve with appropriate antipsychotic medication, while certain hyperactivity

disorders in children are likely to respond to treatment with amphetamines. Clearly accurate assessment in such cases is required in order to choose appropriate pharmacological therapy, as well as to differentiate between those patients who require drugs and those who may be treated exclusively with psychological forms of therapy.

Another difference between the role of diagnosis in general medicine and its role in psychiatry derives from the greater complexities of psychiatric assessment. Assessment of the medical patient involves the diagnostic classification of his presenting disorder, and the choice of appropriate treatment methods. Psychiatric assessment extends beyond these considerations, because psychiatric treatment often involves exploration of subtle aspects of the patient's personality, which, in turn, requires the psychiatrist to understand his patient in depth. Thus, apart from the criteria which usually serve as the basis for formal diagnosis (for example, the presence of specific symptoms such as hallucinations or delusions), the psychiatrist in the course of his assessment must also identify more subtle deviations in cognitive and affective functions; he must assess the quality of the patient's relationship with others; and he must evaluate the degree to which the patient is able to satisfy his sexual, creative, and material needs. The patient's typical modes of adaptation and the strength of his psychological defenses also constitute important data.

In addition to evaluating the current psychopathology, the psychiatrist must attain some insight into the psychological, social, and organic determinants that may underlie the patient's pathological behavior. These might include the patient's most intimate wishes and fears, areas of specific conflict, and distortions in his relationships with other people. The psychiatrist's understanding of the pathogenesis of these phenomena

often requires detailed knowledge of the patient's developmental history. The patient's environment, with its potential stresses and supports, represents still another important behavioral determinant. Finally, the psychiatrist must determine whether organic factors are operative in the genesis of the disorder.

The psychiatrist elicits data about the patient through a variety of techniques:

The psychiatrist's principal diagnostic tool for the accumulation of the complex information upon which he will base his final assessment of the patient is the psychiatric examination, which comprises, in turn, a mental status examination and a psychiatric history.

The purpose of the mental status examination is to assess current psychopathology. Therefore, it is designed specifically to elicit evidence of disturbances in thought processes and affect, in communication, and in social adaptation.

The psychiatric history provides the psychiatrist with a longitudinal view of the patient's personality development and the genesis of his psychopathology. Typically, areas explored in the psychiatric history would include early developmental patterns, intrafamilial relationships and emotional interaction, and the development of sexual adaptational patterns, as well as the identification of specific traumatic events.

While the psychiatrist's evaluation of the patient will depend largely on the patient's answers to his direct questions, other impressions, which may be equally important in terms of their clinical significance, will be based on the patient's nonverbal reactions, e.g., mood, manner of relating, facial expression, and posture. Various interview techniques have been developed to facilitate the examination of specific types of psychiatric patients. These are described in this area, as are the standard procedures discussed above, i.e., the mental status examination and the psychiatric history. The items which are generally included in the mental status examination and the psychiatric history are described, and the rationale for their inclusion is explained. Finally, the diagnostic inferences which may be drawn from the material elicited through these techniques are discussed.

The psychiatrist may suggest on occasion that data of crucial clinical importance have not emerged clearly during the psychiatric examination. For example, he may be aware that the patient has withheld information deliberately but be uncertain of the clinical significance of this material. The psychiatrist may suspect that the patient's illness is more serious than the current psychological status would seem to indicate; he may suspect that the patient is suffering from a severe psychiatric disorder which is in temporary remission. At other times, the psychiatrist may be prevented from

accumulating all the data necessary for a reliable evaluation of the patient's psychiatric functioning simply because he deems it inadvisable to probe certain critical areas in the patient's life experience. And there is still another possibility. Even after the psychiatrist has elicited sufficient data, he may be unable to resolve important problems involving differential diagnosis, e.g., whether the patient's symptoms are psychiatric, neurological, or physiological in origin; or whether what appears to be a severe psychoneurosis is, in fact, a borderline psychosis. In such instances, the psychiatrist has at his disposal additional means of eliciting information: medical and neurological evaluations and a battery of psychological tests may be used for this purpose. In addition, he may refer to the background data regarding the patient which have been accumulated by the psychiatric social worker.

Medical illness may produce psychiatric symptoms which are similar to symptoms which are psychological in origin. The anxiety associated with hyperthyroidism may be difficult to differentiate from anxiety neurosis on the basis of a psychiatric examination, for example, and the depression which is often associated with hepatitis may simulate psychogenic forms of depression. The symptoms in certain forms of epilepsy are characteristic of schizophrenia as well. When evidence indicates that the behavioral disorders which have become evident in the course of the psychiatric examination may be due to organic factors, a medical or neurological evaluation and appropriate laboratory procedures such as an electroencephalogram are required for the establishment of definitive diagnosis.

Psychological test findings also constitute a valuable source of data for the psychiatrist. Projective tests, such as the Rorschach, the Thematic Apperception Test, and the Children's Apperception Test, may serve to illuminate significant wishes, fears, and conflicts which lie outside the patient's awareness, and which in some instances might not emerge during the initial psychiatric interview. In addition, essential qualities of the patient's thinking, the nature and adequacy of his psychological defense mechanisms, and evidences of major psychopathology such as a schizophrenic thought process can be inferred with varying degrees of accuracy, from the patient's responses to the relatively ambiguous visual and social stimuli provided by these tests.

As mentioned above, in some cases the psychiatrist may be reluctant to probe too deeply into the patient's fantasies and feelings by questioning him directly, lest his questions evoke excessive anxiety which may, in turn, precipitate an exacerbation of the patient's psychiatric or psychophysiological illness. Psychological tests of personality function can be particularly helpful

in such cases, i.e., when the psychiatrist requires further information regarding certain sensitive areas of the patient's life which are not readily accessible to direct examination.

Psychological tests of intelligence may also perform an important diagnostic function. The psychiatrist's estimate of this important psychological parameter on the basis of data elicited through the interview may not be reliable. However, the patient's performance on standardized intelligence tests, such as the Wechsler-Bellevue Adult Intelligence Scale, the Wechsler-Bellevue Intelligence Scale for Children, and the Stanford-Binet, usually provides valid and reliable information in this regard. Once these test findings are available to him, the psychiatrist can distinguish between the patient whose pathological behavior is due to a basic intellectual deficiency and the patient whose impaired functioning may be attributed to psychiatric disorders.

Finally, when brain damage is suspected but cannot be clinically demonstrated unequivocally, psychological tests may be of value in determining whether organic factors are operative in the genesis of the patient's pathological behavior. When brain damage is subtle, mild, and diffuse, has developed slowly, or occurs in a "silent" area of the brain, the resultant deficit may not be clearly apparent from the patient's daily behavior; nor is it likely to emerge clearly in the course of the psychiatric interview.

A group of psychological tests has been found useful for the specific detection of minor deficits in such functions as sensory-motor and sensory-sensory integration, the capacity for abstract thought, attention and concentration, and other subtle integrative and perceptual functions which seem to depend on an intact central nervous system. These tests, which include the Bender-Gestalt, Goldstein-Sheerer, and the Rosvold Continuous Performance Test, among other discussed in this area, are often helpful in identifying brain damage which is not apparent otherwise. At the same time, however, it must be noted that these test findings are not conclusive. That is, brain damage may not be reflected in the specific behavior sampled by these tests; "normal" test results do not rule out the presence of brain damage.

In summary, the psychological tests commonly used to supplement and/or clarify the data elicited by means of the psychiatric interview are variously designed to facilitate assessment of particular aspects of personality function, the nature and extent of psychopathology, the patient's intellectual potential, and the possible presence of organic brain damage. The rationale for the construction of each test is explained in Area E, and specific indications for its administration are discussed,

as are the diagnostic implications of test findings and current professional opinion concerning the general validity of such test findings and their limitations. In addition, the techniques for administration of the test and interpretation of the results derived therefrom are described briefly.

The social worker's report constitutes still another potential source of diagnostic data. The patient's environment, especially his social and family environment, plays an important role in both the genesis and the current status of the psychiatric disorders. When this information is not accessible otherwise, the psychiatric symptoms are pathognomonic for specific atoric status will draw on the social worker's assessment of such factors.

In medical illness the same symptom, namely, fever, may constitute the cardinal manifestation of such diverse underlying pathologies as tumor, infection, or allergy. Similarly, outward manifestations of psychopathology are also limited in scope; although some few psychiatric symptoms are pathognomonic for specific disorders, many others cut across diagnostic categories and may be seen in many conditions. For example, anxiety and depression may be the cardinal clinical features of neurotic conflict, brain tumor, the early stages of schizophrenia, drug intoxication, and even a systemic infection, such as hepatitis.

Nevertheless, a description of psychiatric symptoms is fundamental to any discussion of assessment. It delineates the kinds of information the psychiatric examination is expected to produce and the kind of data the student must look for. Accordingly, the third chapter of this area includes a description of the manifestations of psychiatric illness which are encountered most frequently in clinical practice, with specific reference to their implications for assessment and final diagnosis. Psychiatric symptoms are discussed in Area F of this book as well, from another vantage point, namely, in the context of the specific nosological entities in which they occur.

Psychiatric symptoms are characterized by disturbance at many levels of psychological functioning. This chapter has been organized so that the behavioral parameters which seem most "vulnerable" to disruption by psychiatric disorders are discussed, first, in terms of the criteria of "normal" functioning. The discussion then proceeds to consideration of the various behavioral deviations and disturbances which are considered indicative of psychiatric disturbance. The most striking indices of psychiatric illness include thought disorders (which subsume disturbances in association, memory, and judgment, disturbances of consciousness, and disorientation) and distortions in perception; psychomotor disturbances; disturbances in object relationships; psy-

chophysiological reactions; and pathological manifestations of affect, such as anxiety, depression, euphoria, and ambivalence. In addition, psychiatric disorders also manifest themselves in more subtle ways such as work inhibitions, and in an impairment of creative and sexual functioning.

The psychiatric examination is designed to bring to light all of the patient's psychopathological manifestations and to underscore his specific vulnerabilities. Once the psychiatrist has these data at hand, he can formu-

late more specific hypotheses concerning the possible determinants of the patient's illness and plan an appropriate treatment program. It should be noted, however, that the psychiatrist's formulations should include an assessment of the patient's assets, as well as his liabilities. In other words, if therapy is to be effective, the psychiatrist's awareness of the patient's potential capacity for constructive change and growth must remain in the forefront. For, essentially, the fulfillment of this potential is the goal of psychiatric treatment.

Chapter 11

The Psychiatric Examination

11.1 PSYCHIATRIC INTERVIEW

HERBERT S. RIPLEY, M.D.

The interview is the main tool used by the psychiatrist to gain a knowledge of the patient and what is wrong with him. Obtaining a mental status, eliciting a history of the patient's present illness and past life, and carrying out psychotherapy are dependent on a perceptively conducted interview. In fact, all these begin with the initial contact with the psychiatrist. An understanding of the patient in health and sickness comes chiefly from his account of his life events, attitudes, and emotions and of the development of his symptoms. The diagnosis and prognosis are based on these data and the additional information obtained from the patient's relatives, the physical examination, psychological tests, and any other special examinations. With this knowledge, treatment objectives can be formulated, and a plan of therapy that is realistic for the patient can be instituted.

In recent years there has been increasing interest in the psychiatric interview, and important refinements in its use have been developed. The traditional formal examination outline of general medicine has been replaced by greater emphasis on encouraging the patient to tell his story in his own words. The question and answer technique leads to brief and sterile responses and failure to elicit an elaboration of his background. Psychoanalysis has had a great influence on the improvement of techniques in interviewing. Freud in 1905 pointed out that he began treatment by asking the patient to give him the whole story of his life and illness.

The psychiatrist needs to consider not only the implications of the patient's conscious, realistic statements but also the unconscious or transference aspects. By transference is meant the reactivation outside the individual's awareness of attitudes and feelings toward people who were important to him earlier in his life. Infantile feelings of parental omnipotence or of rebelliousness toward parents are frequently di-

rected toward the psychiatrist, who may have trouble understanding such reactions since they are no longer appropriate, as they may have been in the patient's childhood. In his puzzlement, the psychiatrist may feel that his own behavior has been seriously amiss, or he may become angry and blame the patient. The studies of transference relationships by Freud and subsequent investigators have been particularly illuminating of the relationship between the physician and the patient.

Physician-Patient Relationship

The physician-patient relationship is the core of the practice of medicine. It is of concern to all physicians and needs to be evaluated in all patients. Although personality factors are most significant when emotional and mental problems are the core of the illness, they also affect the care of the patient with structural disease. A good relationship, even more than a cure, is expected by the patient; it is common experience that patients are apt to be tolerant of the therapeutic limitations of medicine. Physicians work with sick people, not just disease syndromes. As Alan Gregg put it: "There are no diseases. There are only sick people." Therefore, it is incumbent on the psychiatrist to consider the nature of the relationship, the psychodynamic factors in both himself and his patient that influence the relationship, and the manner in which good rapport can be achieved.

Rapport is the spontaneous, conscious feeling of harmonious responsiveness that promotes the development of a constructive therapeutic relationship. It implies that there is an understanding and trust between the psychiatrist and his patient. With rapport, the patient feels that the psychiatrist accepts him and recognizes his assets, even though they may be outnumbered by his liabilities. Frequently, the doctor is the individual to whom the patient can talk about things he cannot tell anyone else. Most patients feel that they can trust psychiatrists to keep secrets. This confidence must not be betrayed. The patient's feeling that someone knows him, understands him, and accepts him is a source of strength for him.

Physician's attitude toward patient. Failure of the physician to establish good rapport accounts for

much of his ineffectiveness in the care of his patients. Alexis Carrel pointed out that the young physician all too frequently loses sight of the whole man and instead regards his patient as the corpse dissected by the anatomist, the cells and fluids studied by the physiologist, or the consciousness observed by the psychiatrist. However, a live patient brings in a new factor that the medical student's first patient, the cadaver, did not have: transference. The young physician may, in turn, develop a counter-transference, that is, an emotional reaction to the patient based on the physician's own needs and conflicts. The physician identifies with the patient to a greater or lesser degree. Physicians consciously or unconsciously know something about the patient's needs, for everyone has been sick, at least as a child. Thus, the physician develops empathy, which means that he has the capacity to put himself in the patient's place to such a degree that he is able to experience the meaning of the patient's feelings, wishes, and thoughts.

"The secret of the care of the patient is in caring for the patient," remarked Francis Peabody, who was a talented teacher, clinician, and researcher. If a doctor dislikes a patient, he is prone to be ineffective in dealing with him. Emotion breeds counter-emotion. For example, if the physician is hostile, the patient becomes more hostile; the physician then becomes even angrier, and there is rapid deterioration of the relationship. If, on the other hand, the physician can rise above such emotion and handle the resentful patient with equanimity, there may be a victory in the interpersonal relationship, and the patient may become a loyal and cooperative individual. Physicians are bound to like some patients more than others. It is not uncommon for physicians to be emotionally upset by certain personalities or illnesses. However, it is important to try to give a full amount of understanding to all. If the physician feels antagonism, he should try to evaluate the basis for this feeling.

Patient's reaction to physician. The reaction of the patient toward the psychiatrist is apt to be a repetition of the attitude he has had to previous physicians or to parents, teachers, or other authoritative persons who have figured importantly in his life. His reaction may be positive, negative, or ambivalent.

Because the traditional role of the physician is one of taking action and giving advice, patients are sometimes reluctant to tell their stories to a psychiatrist. They come to him with the expectation that all their difficulties will be promptly resolved with no further effort on their part except for a passive compliance with the physician's directions.

Although it is easy for the patient to identify the psychiatrist with another person in his life when there are realistic factors, at times the transference needs are so great that unrealistic factors will serve. For example, a young man can easily look upon an older psychiatrist as a father figure. However, when unresolved conflicts with his father are strong, he may

even endow an attractive young woman examiner with personality characteristics of his father.

The psychiatrist's words and deeds have a power far beyond the commonplace because of his unique authority and the dependence of the patient on him. What the particular physician feels has a direct bearing on the emotional and physiological reactions of the patient. One patient repeatedly had high blood pressure when examined by a physician he considered cold, aloof, and stern. He had normal blood pressure when seen by a physician he regarded as warm, understanding, and sympathetic.

Not only individual experiences but broad cultural attitudes of patients affect their reactions. In one survey of 700 patients, there was substantial agreement among the patients that physicians did not have the time or inclination to listen to and consider the patient's feelings, that they did not have enough knowledge of emotional problems and of the socioeconomic background of the family, and that they increased fear by not giving explanations in nontechnical language. Since psychosocial and economic factors exert a profound influence on human reactions, as has been emphasized by Blum and others, it is desirable for the physician to have as much understanding as possible of the subculture of the patient. Differences in social, intellectual, and educational status have been found to interfere seriously with rapport. Understanding—or lack of understanding—of the patient's beliefs, use of language, and attitudes toward illness influences the character of the physician's examination.

The interrelationship. Lewin pointed out that there is a core of the howling, enraged child in most patients, even in good patients, who are usually defined as cooperative patients. The physician is required to cope with the patient's aggressions. Counter-aggressions also arise, but they are usually sublimated rather than expressed directly, as they were in the days when Dr. Willis flogged the psychotic George III, with the considered approval of a good part of the medical profession. The physician's unconscious guilt, an outgrowth of his incapacity to deal with the patient and his illness, may be alleviated by an accusatory method of questioning, which carries the implication that the patient is responsible for his illness.

Gaining conscious insight into the relationship between the psychiatrist and the patient requires constant evaluation. The better understanding the psychiatrist has of himself, the more secure he feels and the better able he is to modify destructive attitudes. The psychiatrist needs to empathize, but not to the point of assuming the burdens of his patients. He should be able to leave the problems of his patients when away from the office or the hospital. Otherwise, he will be handicapped in his efforts to help the sick person, who needs sympathy and understanding but not sentimentality.

The physician is prone to have some defensiveness, partly with good reason, for many innocent doctors

have been sued, attacked, and even killed because they did not give some patients the satisfactions unconsciously desired. As a protective defensive pattern, the psychiatrist may assume a habitual attitude toward all patients. Although such rigidity may create some comfort and efficiency, it is frequently inappropriate to the particular patient and situation. Greater flexibility leads to a responsiveness to the subtle interplay between two individuals.

The psychiatrist must avoid sidestepping issues that are important to the patient but that he finds boring or difficult to deal with because of his own sensitivities, prejudices, or peculiarities. For example, one medical student insisted on questioning a patient about her relationship with her 23-year-old son. It was evident from the playback of a tape-recorded interview that she wished to talk about her problem with her husband. When the patient was later interviewed by the supervising psychiatrist, she said: "The doctor was a nice fellow, but I could see he was having trouble with his mother. It made me understand my own son more."

In such a complex interaction as the interview, mistakes are usually not disastrous to the relationship if they are relatively infrequent. When the patient senses interest and good will on the part of the interviewer, he is apt to be tolerant of considerable ineptitude. The enthusiasm and interest of the young psychiatrist is likely to counterbalance his inexperience. The unhappy patient is chiefly concerned with getting relief, and the approach of the psychiatrist is more important than his age.

Technique

General considerations. The attitudes of both the patient and the physician are significant in determining the type of interview and its success. The patient comes to the psychiatrist for expert assistance. He may have a relatively realistic attitude characterized by some insight, awareness of the limitations of medical knowledge and skill, trust and confidence in a properly chosen psychiatrist, and capacity to cooperate. On the other hand, he may, like a helpless child, yearn for a parental type of guidance and expect magic from the psychiatrist. When there is such immature involvement on the part of the patient, the psychiatrist may either reinforce this illusion of magic by using a suggestive type of approach or try to dissipate these beliefs through an analysis of the problem.

Some patients come to the psychiatrist under duress because they are sent by relatives or friends. They are prone to be angry, inhibited, and unreceptive. The psychiatrist, through tact and understanding, may win such patients over and develop rapport in spite of such initial difficulties. When the patient shows marked inhibitions, the examiner aims to put him at ease and allows him to talk freely. A receptive manner is helpful. If the patient has questions, they

should be answered frankly. Explanations should be given in keeping with the patient's capacity to understand. Such factors as intelligence, sophistication in regard to personality reactions, and degree and type of illness should influence the vocabulary and content of the psychiatrist's response. Every effort should be made to convey to the belligerent patient both understanding and tolerance for his feelings. If such a patient does not respond and does not wish to talk to the psychiatrist, it is advisable to discontinue the interview and resume contact with him at a later time.

The status of the examiner in the professional hierarchy influences some patients. Those who have had problems with authority may talk most easily to those of lesser status, and those who need to have their security bolstered require attention from a psychiatrist of recognized reputation.

A psychiatrist's knowledge of psychodynamics is of great use in helping him comprehend what is going on and in altering his approach to the patient. For example, if the patient is overbearing, it is likely that he is frightened. The interviewer needs to cope with this underlying fear in order to dissipate the overcompensatory anger. If the patient feels the psychiatrist has empathy, he is likely to talk more freely. It is frequently possible to capitalize on the patient's sense of humor in getting him to talk more easily. Smiling with him helps him feel a sense of rapport. Needless to say, laughing at him alienates him.

In guiding the interview, the examiner should allow the patient's free expression of thoughts and feelings, and he should *let the patient tell his story*. Gaps can be filled in later in the initial interview or in subsequent interviews. Listening is a major tool. Minimum activity encourages the patient to expand on his thoughts and enables him to bring up relevant topics. Attention must be paid to what the patient omits as well as to what he says. Undue emphasis or exaggeration, overt signs of emotion, and changes in manner and tone of voice may give clues to a distortion. For example, when a woman volunteers that her husband is absolutely perfect, her statement should raise suspicions about the soundness of the marital adjustment. But it is not advisable to challenge such dogmatic and emotionally charged statements immediately. These areas can be fully explored later, when the patient feels more secure with the psychiatrist. Misrepresentation and misperception of the facts due to conscious denial or lack of awareness can be clarified gradually.

Evaluating the social pressures existing in the patient's earlier life helps the psychiatrist understand the susceptibility of the patient better. For personality reactions, healthy or unhealthy, are the result of a constant interplay of biological, sociological, and psychological forces. Each stress leaves behind some trace of its influence and continues to manifest itself throughout life in proportion to the intensity of its effect and the susceptibility of the particular human

being. Emotional reactions resulting from strain should be determined in so far as it is possible. The significant point may not be the stress per se but rather what that particular stress means to the person.

The patient must be an active participant when dealing with personality reactions. There is no short cut; he must find out about himself by frankly discussing himself. Patients should be encouraged to discuss the advantages and disadvantages of different possible ways of dealing with a problem. In this way, they learn to make their own decisions and take independent action; and they gain inner security, which will aid in dealing with future problems.

Usually, interviews should not last longer than an hour, although with some alert, receptive patients the initial interview may be prolonged to 1½ hours. Longer subsequent interviews may also be scheduled, especially if it is not possible or appropriate to see the patient frequently. With sicker patients, fatigue and limited productivity indicate that the interview should be shortened.

The ultimate aim is to help the patient change his underlying attitudes and accept emotionally what he has heretofore refused to accept. The patient's confidence in the psychiatrist and his desire to improve can overcome resistance to such change. Resistance implies a conscious or unconscious need to withhold discussion of emotional conflicts. It may be due to shame, guilt, fear of rejection, distrust of the psychiatrist, or a need to hold onto symptoms that provide secondary gain. Frequently, the patient is apprehensive that the anxiety initially associated with his problems will be revived if his repression is removed. Resistance may be shown by talking about irrelevant topics or by directing the conversation to the psychiatrist himself. When patients ask personal questions of the psychiatrist, he may point out that he is interested in the reasons for this curiosity about his personal affairs. However, questions about the psychiatrist's qualifications should be answered frankly.

Question techniques. Questions can be injected when the patient gives appropriate leads. When asked tactfully, questions do not contradict the patient's conception of himself. For example, if a patient who has had three wives complains about the resentment of his present wife, the psychiatrist should not ask him if he has always chosen hostile wives or if he always arouses anger in women. Rather, the psychiatrist should ask whether there have been similar problems with his previous wives.

Leading questions and interpretive comments should be avoided. For instance, if a patient complains of nausea, the psychiatrist should not say, "You must have your nausea when you're at work." He should ask the patient when he has his nausea, and inquire about his environment and his feelings at the time it occurs. The patient himself may then see a connection between the stressful situation and his symptoms.

Thus, instead of becoming defensive because he feels accused, he will be encouraged to develop his own insight.

The perceptive examiner asks questions that will help the patient develop understanding of himself as an individual. The examiner avoids influencing the patient to comply with preconceived theories that do not apply to him. For example, the psychiatrist may want to put all patients with peptic ulcer in the category of those who have unsatisfied infantile dependency needs. Instead, the psychiatrist's questions should lead the patient into an analysis of the development of his symptoms. With this approach, the patient gains an understanding of the hidden meanings of his personality reactions. When sufficient evidence in support of an interpretation has been given, the physician may use this data in making a more direct interpretation. Reformulating the patient's own interpretations may help in clarifying and consolidating insight. There is great variation in the capacity to make introspective observations and to understand their meaning. Those with little ability to revive unconscious thoughts and comprehend inner meanings need the most guidance from the psychiatrist.

Note taking. It is usually desirable to record some verbatim statements as aids in the evaluation of the patient and his illness. Notes should be taken as unobtrusively as possible and should not be so extensive as to interfere with the free flow of the patient's talk. Reassurance that the notes are confidential should be given, especially with patients who feel uncomfortable about them.

Psychiatrists should be alert to the reaction of the patient. When the interviewer feels uncomfortable about taking notes or belabors getting all the data on paper, the patient is likely to have an unfavorable response. If the patient objects to note taking, it is best to discontinue it. On the other hand, many patients object when the psychiatrist fails to take notes. They may consider note taking as a sign of the physician's interest and appreciation of the importance of what is being said.

When notes are not taken during the interview, the physician should take the time to record the data immediately after the patient leaves. However, if no notes are taken during the interview, there is danger that the interviewer's own personality reactions will excessively contaminate the patient's record. So if the psychiatrist doesn't take notes, he might consider sound recordings, which have several advantages over written notes: they are more complete, and they interfere less with spontaneous, easy communication.

Attitudes of the psychiatrist. The psychiatrist needs to listen without reacting, even though he may be reminded of his own disturbing problems or experiences. Therefore, he himself should be relatively well adjusted and have sufficient sources of satisfaction and security. His attitude toward his conflicts must be clarified so that they do not interfere with his

emotional stability and his capacity to concentrate while listening to his patient. The psychiatrist's self-respect is of significance, since ability to respect others is dependent to some degree on one's own self-respect.

Complete passivity on the part of the psychiatrist leaves the patient feeling helpless. However, some psychiatrists go to the other extreme: they pontificate and give interpretations based on their own personal reactions rather than those of the patient. When the patient expresses asocial attitudes, such as murderous impulses toward members of his family, the psychiatrist must avoid showing that he is shocked.

The psychiatrist should keep in mind that it is his medical training and experience that sets him apart. His patients may or may not have greater personal assets than he. The fact that a person needs help with his emotional difficulties by no means constitutes any basic inferiority. So, an authoritarian attitude on the part of the psychiatrist is uncalled for and interferes with the patient's ability to talk easily. Indeed, it is likely to constitute a traumatic repetition of a cultural or parental pattern. Yet many psychiatrists succumb to the temptation to exert authority as retaliation for annoying authoritarian domination to which they themselves have been subjected.

Initial Interview

Since patients are usually anxious and may find it difficult to talk, even under the best of circumstances, the setting should be one where there is quiet, privacy, and freedom from interruption. A comfortable chair should be provided for the patient. The psychiatrist should introduce himself and invite the patient to be seated. A courteous, interested, respectful, considerate, and tolerant attitude on the part of the psychiatrist helps put the patient at ease. The emphasis should be on developing a good relationship, since the relationship determines to a great degree the kind of information the patient will give, and the psychotherapeutic interaction depends on the rapport established.

The psychiatrist should avoid seeming to be in a hurry, since such an attitude inhibits the patient. A stilted, detached, or cold attitude or evidences of anxiety, anger, or indifference alienate the patient. The psychiatrist may develop empathy by trying consciously to put himself in the patient's place.

Asking the patient about the chief problems that brought him to the psychiatrist or hospital is usually the best way to start the interview. The patient can then be encouraged to tell the story of his present illness in his own words. All too frequently, patients complain to psychiatrists that other physicians have not permitted them to talk freely about what they consider important. Listening carefully and perceptively is a major ingredient of the interview. When the patient has the psychiatrist's undivided attention, it stimulates him to unburden himself. One patient said

that he discontinued going to a certain psychiatrist because the doctor read his mail during the interview, and another patient could not tolerate a doctor who habitually munched on oranges.

The conversation should be guided rather than pursued in the manner of a prosecuting attorney. The latter approach leads to frequent "yes" and "no" answers and a failure to gain a depth of understanding of the problem. Simple explanations, reassurance, and praise may be used to obtain information when the patient needs to have his anxiety alleviated. The use of simple English rather than technical terms helps to overcome barriers in communication. However, the physician should avoid the use of slang or swear words. The patient should be accepted in terms of his own ethical and moral values. The psychiatrist should avoid being moralistic, prejudicial, dictatorial, or punitive. He should convey an atmosphere of being authoritative but not authoritarian.

Free expression is a valuable tool. In describing the associative anamnesis, Deutsch and Murphy emphasized allowing the patient to talk freely and making sound recordings for later close scrutiny of what he has said and how he has said it. What is said and the way it is said are of primary significance, but also to be noted are such nonverbal aspects as gestures and facial expressions. Therefore, the patient is asked to give the bodily sensations accompanying his ideas so that the somatic and psychic components can be observed simultaneously. A comparison of the emotional setting of previous attacks and illnesses with the manifestations occurring during interviews gives clues to which factors are more or less coincidental and which are dynamically related to the syndrome under observation.

The patient is frequently more able to talk about himself during the first interview than later, when he has mobilized defenses and resistances. Quiet attentiveness on the part of the physician lessens the development of anxiety, which leads to blocking and silences. But when the patient does stop talking, the psychiatrist should ask a question or two: prolonged silences are apt to be disconcerting. In asking questions, the psychiatrist should repeat the patient's phrases as much as possible so as to minimize the personal distortions of the physician.

What the information obtained means to the patient is highly important. There should be follow through on the leads the patient gives. When the meaning is not clear to the psychiatrist, tactful questioning is indicated. Skillful, discreet, diplomatic questioning enables the interviewer to bring up intimate topics the patient might otherwise be reluctant to discuss. The psychiatrist whose demeanor is comfortable and non-apologetic can be accepted when he asks highly personal questions about such subjects as sex. The more intimate topics can be introduced by asking less emotionally charged questions, such as those concerning physical development. As a natural sequence, the pa-

tient's attitudes and feelings about the topic can be brought up. If the patient becomes unduly upset, the subject should be dropped.

When the patient belabors a subject, change the topic. If he persists in dwelling on it in a garrulous or circumstantial way, it is appropriate to say, "There are other important things for us to cover." Then bring up another subject of possible significance.

There is need for flexibility and individualizing. Flexibility implies altering techniques to suit different patients and to suit one patient at different times. The psychiatrist should develop variations in technique that are suited to his personality. Psychiatrists taught a specific method of interviewing usually deviate in certain ways, although they may conform to the general approach.

Interpretation. Discussion of present problems gives the psychiatrist an opportunity to ask whether there have been similar problems in the past. This approach gives him more information about the past and also gives him insight into the origin of sensitivities. In the first contact with the patient, however, interpretations are to be avoided or, at most, given with the greatest caution, unless the patient has provided unusually strong evidence in support of them. It is better to let the patient reach his own conclusions because then they have more meaning for him.

Avoid pointing out inconsistencies until later interviews, when rapport is well established. Patients need to maintain self-esteem and self-respect. Bringing up his deficiencies is difficult and painful. Since the patient has a need to feel pride in himself, the psychiatrist should not embarrass him.

Terminating the interview. The patient may be warned that only a few minutes more time is available. Such a statement should be given during an appropriate pause rather than injected in the middle of a discussion that seems highly meaningful to the patient. The psychiatrist may point out to the patient that he has asked many questions and then ask the patient to raise questions of his own or to mention something else that he feels is particularly significant.

If no further interviews are anticipated, the psychiatrist can give a brief summary and recommendation. If further interviews are contemplated, the psychiatrist may state that there is need for more discussion, express continued interest, and suggest that the patient think over the topics covered and what he might wish to add during the next interview.

Recommendations for further interviews should be accompanied by a proposed plan for investigation in order to reach a decision about treatment. Or, if there has been sufficient clarification, the psychiatrist may recommend a tentative or specific plan of treatment. It can be simply stated that more time is needed in order to give an adequate opinion. This can be reassuring to a patient who does not want a premature formulation based on insufficient knowledge.

Subsequent Interviews

Subsequent interviews should continue the understanding and therapeutic approach initiated in the first contact. The patient should again be permitted to express what he wishes. If there is a lag in getting started, the psychiatrist may ask him what has been on his mind, how he has been feeling, or what has been happening. The patient may be encouraged to expand on topics introduced during the first interview, or inquiry may be made about areas that were insufficiently covered or were not discussed at all. If during the initial interview there was interruption of a topic that seemed highly significant, the psychiatrist may reintroduce the topic and suggest that they continue where they left off.

To avoid giving excessive direction, the psychiatrist should permit pauses so that the patient can organize his thoughts. If the pause becomes awkward, a question can be asked about the previous statement. Long silences are apt to indicate preoccupation with the thought content concerning personal conflicts, anxiety about revealing too much, or exhaustion of the subject under discussion.

When the patient is having difficulty bringing out pertinent data, questions that will cover his background and clarify his problem are indicated. A play-by-play account of his daily 24-hour pattern is useful. Note under which circumstances the patient feels at his worst and at his best. How do the symptoms affect the patient? Do they fluctuate from day to day? From morning to evening? From hour to hour? Are they affected by eating, exercise, work, social or other particular situations? What brings relief, temporary or otherwise? Are there known precipitating factors, such as worry, accidents, disappointments, bereavements, financial difficulties, or other stresses? Did relatives or friends have similar symptoms, and what feelings did the patient have about them and their illnesses? The aim of understanding and modifying disordered patterns should take precedence over a descriptive classification of the patient. A dynamic formulation of the whole problem is the most significant part of the complete diagnosis.

If the patient shows some asocial behavior, the psychiatrist should continue an attitude of analyzing and understanding; he should not condone or condemn. The patient is apt to withdraw further if blame is placed on him or his relatives. There should be respect for his defenses and opinions. Attention should be paid to the patient's strengths as well as to his problems. The psychiatrist should focus on relevant material, so that coverage is as comprehensive as possible. When rapport has become well established, some challenging of the patient's ideas may be interjected.

Special Types of Interviews

Interview techniques need to be varied according to the personality reactions of the patient, the type

and degree of illness, and the objectives of the interview. Varying degrees of permissiveness and directiveness may be used. Different approaches to different patients are indicated, and the approach to the same patient should be changed when appropriate.

Nondirective interview. This method, as espoused by Rogers, emphasizes minimal activity on the part of the interviewer. When there are pauses, the interviewer repeats the last words of the patient. Rogers has called attention to a significant defect in much interviewing: all too frequently the psychiatrist talks too much, expounds on his own ideas and philosophy, and implants his own ideas through suggestion. When the doctor monopolizes much of the interview time, the patient has no opportunity to express himself.

However, extreme nondirectiveness leaves the patient feeling abandoned and is likely to create considerable anxiety. Only a limited number of well oriented, intelligent patients appear to be suitable for a strictly nondirective approach. Most patients need guidance from an experienced interviewer and are stimulated and reassured by some verbal interchange.

Consultation interview. In a consultation, where it is necessary to give an opinion after a limited period of interviewing time, a more directive approach is required than when a long term therapeutic contact is planned. Therefore, as much essential information as possible must be obtained during the interview. However, such interviews usually lack depth of understanding and therapeutic value to the patient.

Stress interview. This type of interview has its advocates and has a minor place in the armamentarium of interview techniques.

Most patients feel some degree of anxiety or other emotion when talking to a psychiatrist. Through his manner or a word of reassurance or praise the psychiatrist often can decrease this emotion so that the patient can continue to tell his story. However, certain patients are monotonously repetitious or show insufficient emotionality for motivation. Apathy, indifference, and emotional blunting are not conducive to discussion of personality problems. In patients with such reactions, stimulation of emotions can be constructive. These patients may require probing, challenging, or confrontation in order to arouse feelings that will promote progress in furthering understanding. For example, the *la belle indifférence* of the hysteric may be converted into anxiety so that the patient can experience enough discomfort to talk about his conflicts.

Interview with anxious patient. In patients with anxiety attacks, attention should be paid to what thoughts and environmental strains precipitate or increase the anxiety. When the stresses are not evident, prolonged careful investigation may be necessary to elucidate the sources of the emotion. Repressive or suppressive forces may have to be gradually overcome and analysis made of the current situations that evoke feelings. The original stimuli may have been applied symbolically to other people, and much time

and patience are necessary to disentangle the complicated elaborations that have developed. Revival of unconscious mechanisms through such techniques as free association, dream analysis, and hypnoanalysis may eventually result in definitive insights. Endogenous factors and a series of exogenous circumstances, rather than a single traumatic event, are usually responsible for the illness.

Frequently, only vague feelings of apprehension or the bodily accompaniments of anxiety are evident. In such cases, the painful emotion may have been repressed, but it may continue to operate in the unconscious by producing psychopathological reactions.

Interview with patient displaying psychophysiological symptoms. Psychophysiological symptoms are present in a wide variety of clinical syndromes, whether the illness is primarily structural, psychological, or psychophysiological. Such symptoms may be related to either overt or hidden emotions. Careful study of the correlations between stresses, resultant feelings, and bodily symptoms leads to an understanding of the mechanisms. Much psychosomatic research has been concerned with the documentation of such reactions.

When the temporal coincidence of stress, emotions, and physiological reactions is unknown, enlisting the aid of the patient as a collaborator is helpful. Skillful use of this approach in interviewing, and demonstrable measurement of physiological variables, frequently overcome lack of awareness of the psychophysiological relationships and result in clarification of reactions and in therapeutic progress.

Interview with depressed patient. Depressed patients have a short attention span and should have relatively brief interviews. Their tendency to reiterate in a destructive, self-depreciatory way may require active interruption by the psychiatrist. Many patients with depressive illnesses do not make clear statements of mood disorder. Instead they may express their illness through physical complaints or such symptoms as insomnia, diurnal changes in feelings, irritability, or difficulty in concentration. Clarification of the affective nature of the disorder may come by obtaining expressions of futility, hopelessness, self-depreciation, shame, and thinly veiled hostility.

The possibility of suicidal preoccupation should be investigated. The patient may be asked about his interest in life, whether life has seemed to be worth living, and whether he has had thoughts of dying or of taking his own life. If there have been suicidal attempts or thoughts, questions should be asked concerning what he thinks about the reactions of others to these attempts or to his death and what means of suicide he has contemplated.

Since death is a sensitive, taboo topic, the psychiatrist may fear that talking about it will result in an increase in anxiety, depression, or suicidal preoccupation in his patient. He may, therefore, avoid frank

discussion of it. But if questions about suicide are asked tactfully, they are not disturbing and do not increase suicidal ideas. On the contrary, many patients feel relieved to be able to talk to a confidant about such thoughts. Verbal expression may lessen the need to take action. Words of reassurance, such as a statement that death is frequently considered as a possible solution to emotional problems, can be helpful.

Interview with delusional patient. The psychiatrist should show interest, understanding, and receptiveness. He should try to show that he realizes the patient is expressing thoughts and feelings with significant meaning, although the meaning may not be clear at the time. Since the psychiatrist should represent to the patient a person soundly based in reality, he must not subscribe to the patient's delusions. He should neither agree with nor contradict the patient. Rather, he should try to find out more about the nature of the delusional thoughts and who the patient feels is responsible for them. A skeptical attitude may help raise doubts in the patient's mind and may eventually lead him to an understanding of the delusions as an irrational outgrowth of his conflicts or illness.

Interview with the withdrawn patient. If a patient is absorbed with his inner world of fantasy and is unable to talk spontaneously about his feelings, the psychiatrist must be active in asking questions. He should pay close attention to the patient's reactions and should change the subject when there is difficulty in discussing certain areas of conflict. Shifting to subjects that are less disturbing helps the patient accept the psychiatrist and paves the way for the establishment of rapport, which can be used later in discussing topics initially avoided.

In extreme withdrawal, as found in the patient with catatonic stupor, there should be frequent, brief visits. When there is no response to questions about the patient's feelings, the physician may express an interest in talking later to the patient and explain in a kindly manner that he will be available to help when the patient is ready to communicate with him. The mute patient may be acutely aware of what is going on, and care needs to be exercised to avoid saying anything to him or about him to others in his presence that may antagonize and further alienate him. Some seemingly inaccessible patients may show some signs of reacting to the talk of the psychiatrist through gestures or changes in facial expression. Such nonverbal communications should be carefully observed and should influence what is said to the patient. They may be precursors to verbal contact.

Interview with manic patient. Good rapport is not possible with a highly excited patient. The examiner should maintain a calm, receptive attitude and note carefully the thought content. Overtalkative disturbed patients give valuable information about underlying conflicts that they are not likely to bring up when they regain better control of themselves.

Interviewing Relatives

The families of patients can give much valuable data to help the psychiatrist understand the illness, the prognosis, and the therapeutic potentialities. It is important to have contact with them to give them some understanding of the problem and to enlist their cooperation. Similar help can often be gained by obtaining information from friends, associates at work, or other significant people in the patient's life. Most relatives of patients, particularly those of hospitalized patients, want to be acquainted with the psychiatrist and to obtain information about the illness, such as its probable duration and the plan for treatment.

It is essential to interview relatives of children, the mentally retarded, psychotic patients who cannot give a clear history, and patients with character disorders, who notoriously misconstrue or misrepresent facts. Relatives of patients with other illnesses can give significant supplemental information and express points of view that add to the understanding of the problem. When a patient has marital conflicts, it is necessary to see the spouse. Distortions due to thinking difficulties, repressions, and emotional coloring of the data can then be clarified or corrected. For example, a person with a depressive illness may state that he has never been happy and has always been a failure, whereas he has really been successful.

The patient should usually be told about contemplated interviews with relatives before they are held and should be reassured that his confidence will not be betrayed. It can be pointed out that emphasis will be placed on gaining additional information that will be helpful in understanding him and that, during the interview, the relative will be encouraged to do most of the talking. When the patient is strongly opposed to the psychiatrist's interviewing his relatives, the interviews should usually be deferred or not held at all, unless the patient is a child or grossly psychotic. When the patient objects to having his own doctor interview his relatives, the interviews can be carried out by another staff physician or by a social worker, if one is available.

The psychiatrist who identifies with his patient and has heard sharp condemnations of relatives may find it difficult to avoid being antagonistic to the family. Contrariwise, the psychiatrist who is irritated by an uncooperative, hostile patient may be excessively sympathetic with relatives. In guarding against such reactions, he must keep in mind that an understanding tolerance is due both his patients and their relatives.

There are likely to be many discrepancies in the accounts given by different individuals. Relatives are often fearful and antagonistic and strongly influenced by shame because of psychiatric illness in the family and guilt over real or fancied mistakes they have made in relating to the patient. The information from various sources must be evaluated carefully. History

obtained from relatives may have greater validity than that given by the patient. Although it is important to learn what the past events were, it is even more important to know what they meant to the patient and how they affected him. In weighing the data, the psychiatrist must consider the fact that the patient's fantasies may be of greater significance than reality.

Suggested Cross References

The psychiatric interview is designed to elicit information regarding the patient's psychopathology. For a detailed description of the various forms of psychopathology commonly encountered in the clinical practice of psychiatry, see Linn's section on psychiatric symptoms (Section 13.1). Other sources of data about the psychiatric status of the patient derive from the psychiatric history, psychological tests, medical examination, and social service evaluation which are all discussed in the other sections in Area E, on assessment in psychiatry.

which it occurred, the significance of the principal figures in that environment, and the patient's adaptive techniques, such as defense mechanisms and security operations. In short, the history attempts to answer the question: "How did this patient become the person I see before me now?"

The history is also a current commentary. It includes a description of the patient's present environment and the stresses and sources of pleasure that characterize it. It also contains a description of the persons who are significant to the patient, and who now have an influence on him.

There is no one correct form for eliciting or recording the psychiatric history. However, it is important for a student to have a form, so that he learns to cover the important developmental areas. When the student has gained enough experience, he will doubtlessly modify whatever form he has learned to suit his own personality and his own approach. The outline suggested below is offered in this light.

The patient presents himself to the psychiatrist, or he is brought by his family, because of some difficulty he is experiencing. This is the matter that is usually uppermost in his mind during the initial interview. Sometimes, however, a patient who is denying the life difficulty or is unaware of it has uppermost in his mind a desire to impress the psychiatrist with the normality of his behavior and the exaggerated concern of his family. No matter how the patient is presented to the psychiatrist, the current situation or problem is his chief concern. This should always be recorded in the patient's own words and be recognized as the *chief complaint*.

The patient's concern with his present situation does not always match the psychiatrist's desire to understand how the present problem evolved from the past. The psychiatrist's chief asset in eliciting the history is his ability to listen critically. The less threatening he is to the patient, the more the patient will trust him with the details of his personal life. Therefore, the order in which the psychiatrist obtains the history will usually have to differ from the order in which he will record it in final form.

The psychiatric history should be a written document. By recording his data, the psychiatrist is compelled to organize the facts he has obtained into a meaningful story. The most useful form for a history is often a chronological one in which the present illness is shown evolving as part of the individual's life story. When reviewing the written history, the psychiatrist may note what information he has failed to obtain. This review can enable him to become aware of the areas which have not been satisfactorily covered and the questions which may still lack answers. Such study may indicate areas which the patient may have avoided or which the psychiatrist himself may unconsciously have omitted. Becoming aware of these gaps should lead to inquiring after the reason for their existence. This, in turn, may

11.2 PSYCHIATRIC HISTORY AND MENTAL STATUS

WILLIAM L. SANDS, M.D.

The purpose of the psychiatric history is to furnish the psychiatrist with an understanding of his patient's personal development, the environment in

yield fruitful clues for the approaching therapeutic endeavor.

A written history is also a source of information to others. This is particularly true in an institutional setting, where the psychiatrist may be employed only temporarily. Together with the mental status examination, the history should provide a picture of the patient at that particular time, which may be of importance in the future.

The beginner often asks: "How many sessions should be spent eliciting the history?" The answer depends to some extent on the purpose of the psychiatrist's encounter with the patient. For example, an interview to determine an individual's fitness for military service will differ from one that leads to outlining a course of therapy. The latter demands a more accurate diagnosis and evaluation of the individual's personality structure and patterns of adaptation.

In an institutional setting, the psychiatrist may be able to spend several hours a day with the patient to elicit his history and then organize and record the data within the first few days of admission. With an out-patient, this is not usually feasible. Moreover, the out-patient is usually quite concerned with how his current stresses and discomforts interfere with his job or home situation. Therefore, the first few sessions represent a combination of maneuvers, permitting the patient some time in which to focus on the present situation but also, for a part of each session, directing his attention back to the developmental periods so that the psychiatrist may arrive at a dynamic formulation, establish a tentative diagnosis, and plan the optimal therapeutic approach. This is usually done with the indication that, once the history has been obtained, the therapist will have fewer direct questions and the patient will be expected to carry more of the sessions' direction by sharing the thoughts that come to mind.

The psychiatric history may arbitrarily be divided into eight sections: (1) identification of the patient; (2) chief complaint and present illness; (3) personal history; (4) family history; (5) mental status examination; (6) physical examination; (7) psychodynamic formulation; and (8) diagnosis, prognosis, and recommendations.

Identification of the Patient

This should include the following details: name, age, sex, ethnic and cultural background, marital status, occupation, and means of referral. It may include a statement about the patient's housing situation. If the patient is being admitted to a hospital, the section should indicate whether this is the first such admission or whether this admission represents a rehospitalization for his psychiatric disorder.

Chief Complaint and Present Illness

Chief complaint. This should always be stated in the patient's own words. Although the patient's fam-

ily may view the problem quite differently, the manner in which events are perceived by the patient himself will be of the greatest importance to the examiner. There will be times when the subtleties of the patient's perceptions may not be apparent to the psychiatrist until some time after their collaborative effort has been under way. A verbatim record of the chief complaint permits the psychiatrist to review it periodically in the attempt to learn why events appeared as they did to the emotionally disturbed patient. Improvement in the psychotic patient may be gauged in part by his own ability to reconsider earlier perceptions of his situation. As the patient improves, he and the psychiatrist may acquire understanding of how distorted perceptions came about. Although both patient and doctor may not succeed in achieving this understanding, they should certainly strive to acquire it.

Present illness. This section must set forth the story of the present illness as the patient has become aware of it.

Interviewing the patient. The psychiatrist will rarely obtain the history of the present illness in chronological order. The usual patient will be somewhat repetitious in discussing his illness, giving emphasis to those aspects that most trouble him. He usually intersperses his story with digressions and follows association trails that may be extremely informative to the psychiatrist even though they are not directly related to the present illness.

In eliciting the history, the psychiatrist must listen patiently, permitting the patient to tell his story spontaneously, and must carefully observe the patient's behavior, changes in posture, intonations, facial expressions, and emotional reactions to the various subjects discussed. If the patient is spontaneously productive, it is wise to permit him free rein in giving his account of what has befallen him and to limit questions as much as possible. The patient must be aware of the psychiatrist's sympathetic interest and willingness to be helpful; and, it is hoped, he will perceive the psychiatrist's respect for him as an individual. Especially at this stage, the patient must learn that, no matter what he has to report, the psychiatrist, in contrast to his family or friends, will listen uncritically and will not argue or scold, attempt to deny the patient's perception of events, or ridicule him for reporting strange ideas.

If the patient does not report any stresses or events which may have precipitated the present episode, the psychiatrist must inquire about them. He must obtain a clear description of each symptom or sign of illness of which the patient is aware. Where a symptom constitutes a prominent part of the illness, the details of its first occurrence must be obtained. The social context in which symptoms arose must be presented clearly.

The report. From the wealth of data that the examiner has obtained, he must extract and or-

ganize those items which will provide an intelligible and sequential presentation of the development of the present illness. This presentation is rarely in the same order in which the psychiatrist has obtained the data. Not infrequently, organizing the data into such a structured history will bring to notice significant connections of which the patient may not have been aware and which may have therapeutic import.

This section should record whether the patient has encountered such difficulties before. If there were previous occurrences, the dates and outcome of each episode should be included. If there were earlier psychiatric treatments or previous hospitalizations, they should be recorded here, giving the name and address of the psychiatrist or the hospital and dates of admission and discharge. With written consent from the patient, summaries of previous hospitalizations should be obtained. The mode of therapy employed and outcome of each hospital admission should be recorded. If there were hospitalizations for non-psychiatric illnesses, they should be indicated in the next section, the personal history.

A psychotic patient may be unable to give a description of the current problem and may even deny that any exists. In such a case, the informant who supplies the information should be clearly identified, his relationship to the patient stated explicitly, and the problem reproduced in *his* own words. It may occasionally be advantageous to have statements about the problem from several informants.

Personal History

The history of each period of the patient's life—infancy, childhood, adolescence, and adulthood—should be described separately. If the history is written in this chronological fashion, the behavior patterns which the individual has developed as he has matured emerge clearly; the environmental forces that have helped form them will also become apparent. Similarly, limiting physical or social factors can also be appreciated and their effects understood in relation to the period in which they occurred. The present illness may then be seen as the inevitable consequence of the patient's life story. For each period, the psychiatrist should record his survey of the patient's social, sexual, and vocational functioning, along with the inhibitions imposed by excessive or inappropriate fears and guilt, and the sources of the patient's successful pursuit of pleasure.

Infancy. Here first-hand data can be obtained only from parents. The patient and other informants can merely report what they have been told. The psychiatrist wishes to learn all he can about the physical and emotional climate into which the patient was born. Therefore, he attempts to learn whether the patient was a planned child; what the physical health of the mother was during pregnancy; what the nature of her relationship with the father was at that time; some details concerning the labor and delivery; the

health of the patient during the neonatal period; the age at which he first sat up, walked, and talked; the method of toilet training used and the age at which sphincter control was achieved. An attempt should be made to discover what the patient's patterns of eating and playing were and what his parents' attitudes were to his behavior as an infant.

Physical motility. Infants display considerable variation in physical motility. Some are relatively passive; even when hungry, they may display little more than increased eye movement or head turning. Others inform their mothers of hunger or other discomfort with loud noises, much crying and thrashing about in the crib, and sucking movements that may eventually carry the baby's whole fist into his mouth. There are indications that much of this variation is inborn, but parents may respond to it with attitudes ranging from guilt or displeasure to pride, depending on what they think their baby *should* display. When the infant's behavior does not meet the parents' expectation, a cycle may be established: disapproval from the parent, stemming from his own anxiety, engenders anxiety in the infant, which then causes more anxiety in the parent. Such cycles sometimes constitute the dominant pattern of interaction between parents and growing children and often have serious emotional consequences.

Sleeping patterns. A similar inquiry should be made into sleeping arrangements. It is desirable to know what they were during infancy, and whether and when they were subsequently altered. If an infant shared the intimacy of his mother's bedroom but was displaced by his father's return from military service or the birth of a sibling, the displacement could play a major role in his subsequent emotional development and affect his relationship with his father or sibling.

Significance. A child's normal emotional development is related to his mother's ability to nurture him. Therefore, information concerning the mother's emotional and physical health during pregnancy and during the patient's infancy is of great importance. Whether the mother was able to feed and care for her baby in a patient, tender, and loving manner is of more significance than whether he was bottle-fed or breast-fed.

The way in which toilet training was carried out probably exemplifies the subsequent relationship between the patient and the mother. The mother who is severe in this matter is often equally strict in setting other standards for the child to meet during the first decade of development.

Serious physical illness during the first year of life, in which such vital functions as respiration or feeding are threatened, may initiate life-long anxiety in the child. Physical illness that leaves permanent residue or congenital defects that limit the attainment of physical skills damage the growing child's self-confidence and self-esteem, qualities which will be necessary for his success throughout the remainder of childhood and, indeed, into adulthood.

Childhood. This section can be divided into two periods: from age 1 up to entry into school, and from then until the onset of puberty. Here, as in the section concerned with infancy, the psychiatrist needs

to gain an understanding of the physical and emotional climate in which the patient was raised. He attempts to learn what the patient's personality was like during those childhood years and whether there were marked changes in dominant personality patterns and, if there were, what caused them. He tries to elicit a history of the usual childhood illnesses and how they were tolerated by the patient and his parents; a history of other illnesses, injuries, or hospitalizations, with emphasis upon the emotional reaction to them by the patient, his parents, and other people important to him; and a history of serious illnesses or deaths in other members of the family and how they affected the patient. The psychiatrist attempts to learn the patient's reaction to beginning school and to the subsequent school years; the history of any truancy, school phobias, academic difficulties, or outstanding achievements; the level of his academic performance; the pattern of his relationship to peers both in school and outside; his reaction to any moves from one school to another; and family attitudes toward such activities as school performance, religious instruction, church attendance, music lessons, athletic participation, etc.

It is important to note whether the parental expectations were consistent with community norms or significantly deviant. If the latter, how did the parents justify themselves to the child, and how did he accept the parents' standards? What was the relationship between the parents during this period? To what extent did the child observe affectionate display between his parents, and to what extent was affection openly given to him? The variation in family attitudes toward open display of affection or candid acceptance of children's sexual curiosity is still very great in our society. What was the parents' attitude to the child's sexual curiosity and to any questions he may have asked about sex? How did they react to childhood sexual experimentation?

Other data to be described in this section include the patient's reaction to the birth of younger siblings; the nature of the siblings' relationship as they grew up; whether the child played alone or usually with playmates; and whether there were enduring friendships or frequent changes of playmates. In stress situations, did the patient show somatization responses? If so, of what sort were they, and were they recognized as being emotional in origin by the parents?

The psychiatrist also attempts to learn evidences of the patient's sexual interest or activity. What outlets were permitted him for expression of hostility; what evidences of excessive or inappropriate fearfulness became manifest; was there a history of nightmares, temper tantrums, enuresis, or nail biting; what avenues for pleasurable experience were provided; and what techniques did the growing child employ to bolster self-esteem and self-pride?

Here again, as in the section concerning infancy,

an inquiry into sleeping patterns and sleeping arrangements must be made.

Significance. In childhood, as in infancy, attainment of appropriate skills increases pride and self-confidence and encourages the individual to experiment further with his ever expanding universe. During this period, the accepted standards of society must be learned so that the child can function away from home, at school and at play, and learn that he can operate successfully without the constant surveillance of a protecting parent.

In learning the rules of his particular society, the child inevitably undergoes some frustrations. If the consequent anger is not to be internalized, he must be permitted outlets for its expression. The psychiatrist must learn what the patient was forbidden by his family and what he was allowed, and how successfully this formula was integrated into his personality. What techniques were available to the growing child for expressing anger? Were his independence and self-reliance fostered or inhibited? Some of this information will come to the psychiatrist as concrete evidence; but some he will have to deduce. He should, of course, distinguish between concrete information and deduction in his report.

The significance of childhood illnesses depends particularly on the reaction of the parents and on how much anxiety they may have transmitted to the child. The child's life-long attitude toward illness is determined in large part by what happens during these formative years. For example, there are some individuals who respond to illness as though they were invulnerable or even immortal and others who react to a minor upper respiratory infection as if it were a serious disease. Some people minimize physical illnesses, while others dramatize them and appear to delight in telling friends the details of every symptom. These different attitudes originate early in life, as a result of attitudes toward medical treatment and relationships within the family.

A further illustration contrasts treatment attitudes. A generation ago, all children who had rheumatic fever were kept in bed for periods of 6 months to a year, with their physical activities permanently restricted thereafter. Now practice calls for continued activity, depending on the patient's physical condition. The emphasis is on maximum participation in all the activities in which the child's peers engage, so that his self-image is not damaged and he does not develop false ideas of required immobilization.

Adolescence. The same questions asked about previous developmental periods must be reviewed here. The goal is to ascertain the adolescent's adaptive techniques for building self-pride, coping with anxiety, and expressing anger. The particular demands made upon him during this period are both biological and social, the one relating to the onset of puberty and the appearance of sexual impulses, and the other to his scholastic preparations for a career.

The psychiatrist attempts to learn what the patient's reaction was to the physical changes of puberty: for the girl, emotional reactions to breast development, preparation for menarche, circumstances of and reaction to first menstruation, pattern of reaction to subsequent menstrual periods; for the boy, preparation for nocturnal emissions, reaction to them and to spontaneous erections; for both sexes, masturbation fantasies and behavior, homosexual episodes, heterosexual behavior, and dating patterns. The reaction of the patient's family to his adolescent sexual behavior is also an important part of

this historical development. Was the family's attitude consistent with that of the community or at variance with it? Did the parents instill feelings of guilt in response to the patient's inevitable sexual curiosity? The absence of memories of sexual thoughts during adolescence indicates an inhibition fostered by parental attitudes, which condemned sexuality on moral grounds. How much guilt was engendered by masturbation? Under what circumstances did the patient acquire sexual information? In what situations did sexual behavior first occur, and what was the adolescent's subsequent emotional reaction?

The psychiatrist should also ascertain whether the adolescent was isolated or whether he was accepted by his peers and found membership in some group, thus building self-esteem. Were there abrupt changes in the patterns of relating to others?

School performance may be one guide to the adolescent's general functioning. It is also an indication of his ability to organize his energies into constructive patterns and of his capacity to plan meaningfully for adult responsibility. How much day-dreaming occurred, and to what extent did fantasy fulfillment take the place of realistic goal planning? What were the evidences of rebellion against family standards in the patient's attempt to forge his own identity? Or were family standards accepted, and to what degree?

Significance. The adaptive patterns the individual unconsciously develops to survive in his particular environment become clearer as he nears adulthood. Many emotional difficulties become apparent during this period if the adaptive techniques prove inadequate to the increasing social, vocational, and sexual demands made on the adolescent by his body or his environment. If the adolescent encounters defeats in some areas, he may be less inclined to try again. Withdrawal from social relationships or from previously enjoyed activities are clues to malfunction. If the adolescent avoids activities in which his peers participate, the reason for the avoidance should be elucidated. The psychiatrist may suspect the existence of excessive or inappropriate fearfulness and attempt to confirm his suspicions. This, in turn, should lead to an identification of the substitute activities through which the adolescent attempted to compensate for the social defeats represented by his withdrawal and for the consequent damage to his self-esteem and pride.

The relative amounts of passivity and self-assertion that characterize the patient become clearer during this period and establish themselves more firmly as patterned behavior. The psychiatrist should learn how these modes developed in the patient. Which were subtly or openly encouraged by the family? Which techniques did the patient apparently find successful in achieving acceptance by parents and other significant figures? If the adaptive patterns that were successful in achieving emotional security in the family are unsuccessful in coping with others in the outside world, the child often becomes confused and uncertain. The psychiatrist must learn whether the patient resolved this and similar conflicts by adopting more successful survival techniques or by withdrawing from the competitive struggle. Withdrawal always signifies defeat and results in decreased self-esteem.

In order to participate successfully in society as an adult, the adolescent must integrate into his personality those techniques necessary for achieving a relatively happy and mature adaptation. These include such qualities as healthy self-asser-

tion, vocational capacity, a realistic self-image, and an ability to form relationships with others characterized by candor, trust and sincerity. It is important to note that societies other than our own may emphasize other qualities. The standards that an individual must aspire to are determined largely by the society of which he is a part.

Among the experiences that increase self-confidence are those that require some initiative. Often these include some experimentation with behavior which the adolescent knows does not meet strict parental approval. In every generation, such experiments and other adolescent rebellions have engendered anxiety and reproach among adults. When the United States was primarily a rural country, such rebellion was exemplified by smoking cornsilk behind the barn and sparking in the family buggy. Today, in our largely urban society it appears to be manifested mostly in sexual behavior, echoing society as a whole, which has moved away from the double standard.

The psychiatrist must learn whether the patient was able to experiment with new ideas during adolescence. These need not have been in the sexual area only. It is not unusual for adolescents to question religious practices or affiliations. The psychiatrist must learn whether such attempts by the adolescent to forge his own identity were acceptable to parents or whether they were condemned and, if so, how severely. If adolescence was entirely free of such rebellious episodes, it may mean that self-assertion was inhibited. Such inhibition should then show up in other behavioral foci. Evidence of guilt should be noted, along with evidence of exaggerated conformity after attempts at rebellion which had been defeated by what the adolescent perceived as excessive parental disapproval. If the patient did conform in this way, the psychiatrist must look for signs of disproportionate fear in his subsequent behavior.

Mature, emotionally secure parents recognize that adolescents need to learn from experience, and they permit experimentation while providing guidance when it is sought. The parents' own practices, which sometimes differ from what they preach, are known to the adolescent. His ability to adopt parental standards as his own eventually or to reject them is an indication of a secure parent-child relationship.

Adulthood. The onset of adulthood is arbitrarily delineated for the purposes of history taking. Graduation from high school may conveniently end the section on adolescence, but adulthood may truly be said to begin when the individual moves from his parents' home and becomes self-supporting. Entry into college is frequently associated with leaving home, and for many individuals it represents the beginning of adulthood.

Whether the patient goes from high school directly into college, into the labor market, or into military service, the history must record whether or not the move was a result of his own desire and planning, and what his reaction to it was. It must show how the patient attempted to satisfy prestige needs; how he coped with fears, anxieties, and hostilities; and whether his techniques for doing so differed from methods employed earlier. Did he allow himself to become aware of anxious and hostile feelings, or did he have to deny them? Were these feelings accompanied by excessive or inappropriate guilt, and did this represent a change from previous patterns?

Career planning, sexual experimenting, courtship, and marriage—all should be described in this section;

their pattern will probably be consistent with the patterns for handling emotional drives which have been seen evolving throughout the history. The psychiatrist should be alert to repetitive patterns manifested in job performance and in social relationships. If there were many job changes, why did they occur? Does the patient always ascribe the precipitating cause to factors outside himself, or does he recognize his own degree of responsibility? Is the patient able to develop close relationships, or are his relationships always casual? Does he maintain friendships, or are they always short-lived and changeable? What evidence is there of his capacity to love others? Is he exploitative toward his girl friend, wife, or children? Does he give as well as take? The history must record evidences of emotional crises and difficulties as the patient progresses through adulthood; it must tell how they were resolved, and whether they recurred. It should also note, as in earlier periods, the effect on the patient of physical illness, and of the diseases and deaths of parents and other people who are important to him.

Marriage. If the patient has been married, a detailed history of the relationship must be included. What first attracted the patient to the partner? Which person took the lead during courtship? What difficulties were encountered? Did either family object to the relationship? If so for what reasons? To what extent did the couple understand each other's goals for the marriage? Were they able to discuss such potential areas of difference as church affiliation? Were children desired? Since raising a family is a cultural expectation, it is of great importance if either partner did not want children. If both desired to have a family, did they agree on its size? Were they in agreement about contraceptive techniques?

What has been the history of the sexual relationship during the marriage? Merely recording the fact that the patient enjoys sexual intercourse does not provide the type of information the psychiatrist requires. What is the usual coital pattern? Who takes the lead in initiating sexual activity? Are both partners orgasmic? Is there a history of impotence or frigidity? Have there been abortions? How did the patient react to each pregnancy and each childbirth? Which were planned and which were not? What is the history of extramarital episodes? What was the patient's emotional response if either he or his mate proved to be sterile? Did the couple adopt children? If so, how did they go about it?

Significance. The psychiatrist must view alleged motivation critically, knowing that manifest behavior often serves to hide unacceptable impulses and tendencies. For example, marriage may sometimes represent refuge to an individual tormented by unacceptable homosexual impulses. Marriage may represent an easy escape from the frightening challenge of college discipline, or it may express spiteful defiance of parents. Of course it may also represent a mature readiness for self-realization and the ability to take an adult place in the community. A detailed history of the courtship and marriage can indicate to the psychiatrist the extent to which the

patient relies on wishful thinking instead of planning maturely to reach his goals. When wishful thinking does occur, its effects are usually evident in other areas of behavior as well.

The significance of abortions may not be revealed until later periods of emotional depression. During depressions occurring in the 5th or 6th decades of the patient's life, the psychiatrist frequently hears expressions of remorse and guilt concerning abortions that occurred twenty or more years earlier.

When listening to descriptions of children, the patient's psychiatrist must also be alert to any correlations that there might be between the patient's attitudes toward them and his attitudes toward his own siblings or other significant persons in his family of origin. Often, the patient's attitudes towards his children represent unconscious displacements of emotion from significant figures of his childhood.

Family History

This section should include a description of the parents and siblings in the patient's family of origin. Although some mention of these important persons probably occurred in the patient's account of his life history, they should be described individually and in greater detail here. Their names, ages, occupations, economic and social status, marital records, and history of physical and emotional illness should all be recorded. In particular, the psychiatrist should inquire about the possible occurrence of depression, psychiatric hospitalization, suicide, alcoholism, drug addiction, mental retardation, convulsive disorders, or syphilis.

In addition to these factual data, this section should indicate how the patient felt about each of these relatives, what the nature of their relationship was during the patient's childhood, and what it is like now. If there were divorces or marital separations, what was his emotional response? Was it different from that of his parents? A similar description of the patient's spouse and children may be made here or in the preceding section.

Mental Status Examination

The purpose of recording the mental status examination is to enable the psychiatrist and others who may need to review the chart to obtain a precise picture of the patient's emotional status and mental capacity and functioning. Therefore, verbatim samples of the patient's speech and thought content should be included.

For clarity, the mental status examination should be recorded in a certain order and organized according to certain categories. However, these need not be the order in which the examination itself is conducted, for that order usually depends on the circumstances under which the patient and psychiatrist meet, the degree of cooperation of which the patient is then capable, and the degree of intactness of his sensorium. In any particular situation, the examiner must exercise his own judgment about which parts of the mental examination are to be emphasized.

Even if a patient is inaccessible or stuporous, it is

nonetheless important to attempt the mental examination and to record the findings. Not only does this provide a picture of the patient *at that time* to someone reading the case record later, but the description of the patient is valuable as a base line for future comparison.

Interview behavior

Relationship to psychiatrist. Was the patient cooperative, indifferent, or withdrawn? Did he welcome the opportunity to present his views to the psychiatrist? Did he recognize the purpose of the interview? Was he openly hostile or assaultive? Did he display a friendly attitude? If so, was it excessively friendly or inappropriately "chummy?"

What is needed here is a general view. A specific description of the patient's emotional reactions is to be presented below.

General appearance and grooming. Was the patient dressed with normal neatness? Were the clothes he wore appropriate to the season and the occasion? Were they clean and in good repair? Was the patient clean? Was his hair combed? Were his fingernails cut?

Motor behavior. Here the psychiatrist presents a picture of the patient's over-all motor behavior during the interview. Were his motor acts appropriate to the situation? Were they smoothly coordinated, jerky, or awkward? Was there hyperactivity? If so, give a careful description.

Was his motor behavior purposeful or seemingly aimless? Was any motor act self-injurious or destructive of objects in the room?

Was the patient willing to shake hands in greeting? Was his handshake of normal firmness or was it abnormally limp? Was there evidence of cogwheel rigidity or waxy flexibility? Did the patient display wringing of the hands, tics, twitching, or a tremor? If so, was it constant or "on intention" only?

If the examiner suspects that the patient is abnormally slowed, he may time the patient's reactions by giving him simple commands, such as asking him to walk across the room, to untie and tie his shoelaces, or to write out a dictated sentence. In the report, the examiner should give the time it took the patient to respond. The patient should be given a simple explanation for the test, such as, "I want to see how long it takes you to do certain things."

Posture. Was the patient normally relaxed, stiff and guarded, or limp and sprawled out in the chair?

Gait and carriage. Did the patient carry himself erect or slouched over? Was his gait normally brisk, slow, desultory, dilatory, unsteady, or poorly coordinated?

Facial expression. Was the facial expression appropriate to and consistent with the subject under discussion? Did it change appropriately with change of subject? Was the patient's face unexpressive and flat? Did he look to be normally attentive, apathetic,

or indifferent? Did the patient at any point show elation (to what degree: mild pleasure, appropriate smile, or uncontrolled laughter); fear (to what degree: mild anxiety or apprehension, crying, or absolute terror); or anger (to what degree: frowning, scorn, or rage and fury)?

Voice and speech. Evaluation of the patient's speech should include consideration of the following factors: (1) Intensity. Was the patient's voice normally audible, excessively loud, or excessively soft? (2) Pitch. Was his voice monotonous or did it show any abnormal changes in pitch? (3) Speed. Did the patient speak at the usual rate of speed, very slowly, or rapidly? (4) Ease of speech. Did the patient speak easily, under much pressure, or hesitantly? (5) Spontaneity. Was his speech spontaneous, did he respond only when questions were put to him, or was he mute? (6) Productivity. Did the patient speak with usual verbal productivity, or was he garrulous, or laconic? (7) Relevance. Were his productions relevant, flighty, or easily distractible? (8) Manner. Was his manner of speaking pedantic, excessively formal, relaxed, or inappropriately familiar? (9) Deviations. Was there evidence of neologisms, echolalia, clang associations, or verbigeration? (10) Reaction time. Was it appropriate or abnormally slow? If significantly slow, the psychiatrist should time the interval between asking a question and obtaining the patient's response. (11) Vocabulary and diction. Were his vocabulary and diction consistent with his social and educational background?

Disturbances in speaking may occur at certain times during the interview, depending on the material under discussion. Themes of special emotional significance to the patient may produce alterations in any of the above qualities. Special note of this should be made when it occurs.

Emotional reactions. These are best recorded in the patient's own words. It is important to note the consistency of his stated emotion and its appropriateness to the subject under discussion. The examiner must note any inconsistency between the emotional reactions which the patient reports and those which he is observed to be having.

If the patient does not report his feelings spontaneously, questions designed to elicit a statement about them may be helpful. If asking the patient how he feels does not obtain the desired information, more specific questions should be asked. Are you sad? Happy? Fearful? Are you worried about something? Does something hurt you?

For the unresponsive patient, the examiner must note signs that suggest certain feelings. These include his observations of the patient's facial expressions and their changes, pulse and respiration rate, tearfulness, sweating, and blushing.

Content of thought. What does the patient speak about spontaneously? How does he account for having come to the hospital or to the psychiatrist's office?

It is preferable to let the patient give an account of his problems without interrupting him with questions. However, there may be times, as with a patient who is easily distracted, when the examiner wishes to focus the interview more sharply. In examining a patient who does not voluntarily share his thoughts, the psychiatrist may ask: What are your worries? How did they come about?

Are there subjects about which the patient refuses to speak? Evasions and outright refusals to speak are as significant as the patient's answers, and they should be noted.

Persecutory trends. These may be elicited by asking: Do you think anyone is against you? Do people say things about you behind your back? What does it seem they say? When you get on a bus or a train, do you feel the other people turn around to look at you? Do they watch you during the entire ride? Is anyone trying to control your mind? How are they attempting to do this? Why do you think this is happening?

Hallucinations. To test whether the patient is hallucinating, the psychiatrist can ask: Have you ever heard anyone call your name aloud and, when you turned around, found no one there? Do you hear other things without discovering their source? What things? If the patient can identify a voice or voices, then the examiner should ask: Whose voice is it? Is it a man or a woman? Do you hear more than one person? Do you hear this in both ears? What is the person saying? Is it pleasant or unpleasant?

Do you ever see strange things? Do you ever see things you know are not really there? How do you think that comes about? What do these things look like? Do they frighten you? Are they moving or still?

Do you smell strange odors or feel things on your skin when you cannot see anything there? Do you have unusual tastes in your mouth? When does that occur? What brings it on? What is the strangest experience you ever had?

The examiner may believe that the patient is responding to hallucinations even though he denies it or declines to confirm the examiner's suspicions explicitly. In such instances, the examiner must carefully record what he has actually observed. Did the patient turn his head suddenly? Did his eyes appear to be following something in motion? Did he stare at a particular place in the room? Did his gaze return to a particular place at intervals during the interview? Did he mumble or appear to be conversing with a third person?

Hypochondriacal trends. These may be elicited by asking: How is your health? How do you sleep? Are you often ill? How frequently do you usually visit your doctor? Are there any special foods in your diet? Do you take any medicines regularly? What do you keep in your medicine cabinet? The examiner may wish to be even more precise in certain cases and

ask questions such as: How is your heart? Your bowels? Blood? Sexual organs? Brain?

Schizophrenic trends. Ideas of unreality, which may characterize an incipient schizophrenic episode, should be asked for. Do you ever feel outside yourself? When crossing a street, do you ever feel as though someone else is moving your legs? Does the world look different to you? How? Do things about you sometimes seem not to be real? Does their size seem to change?

Depressive trends. When present, depressive trends are usually mentioned by the patient himself. However, it may be helpful to ask: Do you think you are going to get well? Are you blue? Have you ever thought of hurting yourself or committing suicide? Did you ever try to do something like that? Do you think you are a wicked person? Why?

If the patient is severely depressed, he is rarely spontaneous in describing his ideas. Severely depressed patients will often acknowledge nihilistic thoughts. These may be elicited by asking: Do you think everything is hopeless? That the world has stopped? That things outside no longer exist? That tomorrow will not come?

Ideas of grandiosity. When present, grandiosity is usually indicated by the patient himself. He may describe himself in exalted terms. He may exaggerate the amount of his wealth or the number of automobiles or homes he owns. It may be helpful to ask: Do you receive messages from God? Do you have any unusual powers? What is your real rank? Do you think people recognize who you really are?

Compulsions. These may be asked about with questions such as: Are there any habits that you have? Are there any things you feel you must do in a certain way? More specifically, the examiner may ask: Do you have to wash your hands in a particular fashion all the time? Or bathe or shower in a certain way? Or use the toilet in a certain way? Is there anything you must do first in order to be able to fall asleep?

Obsessive thoughts. Such thoughts may be elicited by asking: Are there any thoughts that continually run through your mind? Are there certain prayers or particular slogans you feel compelled to say to yourself? Under what circumstances?

Phobias. When present, phobias are usually spontaneously described. However, the examiner may inquire: Do you have any particular fears? Do you have any morbid fears? Are there any places you feel you must avoid? Why? Are you able to use elevators? Do you feel you cannot go to the upper floors of tall buildings? Or into subways? Or to church? Or to any particular neighborhood or street intersection? When did you first become aware of such a problem?

Sensorium. This section describes the patient's state of consciousness and his ability to perceive his

environment correctly. The following items must be tested:

Orientation

Time. Does the patient identify the date correctly? If not, is he approximately correct? Can he give the month? Year? Season? Time of day? If he is in a hospital, does he know how long he has been there?

Place. Does the patient know where he is? If he is in a hospital, does he know its name and location?

Person. Does the patient know who he is? Does he know who the examiner is and what he represents? Does he perceive the hospital staff and other patients correctly?

Recent memory. This may be tested by asking the patient: Where do you live? What is the address? What are the names of the other people who reside there? How did you come here? With whom did you come? What have you eaten today? Where did you go yesterday? What was in the newspaper or on the radio news program today?

The particular questions to be chosen for testing recent memory depend on whether the patient is hospitalized or is being seen as an out-patient.

Remote memory. This may be tested by asking the patient: Where were you born? What was the date? Where did you grow up? What was the address? Where were your elementary and high schools located? What were the principals' names? How far did you go in school? How old were you when you took your first job? Where was that? How long have you lived at your current address? When were you married? What was your wife's maiden name? What are the names and birth dates of your children? What are the names and addresses of your siblings?

Questions must be appropriate for the particular patient. Thus, if the patient has been hospitalized previously, he may be asked when and where that was, the names of previous physicians, and the locations of their offices.

For foreign-born individuals, dates of immigration and naturalization are important and should normally be within recall. Similarly, questions designed to reveal their mode of travel to the United States may be included.

Retention and immediate recall. These faculties may be tested by giving the patient a date or the name of a person and asking him to remember it, as he will be asked for it later in the interview. The examiner should then test him after 5 minutes and again after 20 minutes or toward the end of the interview.

Auditory memory span may be tested by asking the patient to repeat a series of numbers. The patient should be able to recall and recite at least seven numbers forward and five numbers backward without error.

Visual memory span may be tested by pointing to an object or to the time on a watch and asking the

patient to remember them. The examiner should then test the patient after 5 minutes and again after 20 minutes or toward the end of the interview.

Counting and calculation. Intactness of these functions may be tested by asking the patient to count to 20 forward and backward; to subtract 7 from 100 and to continue subtracting serially. The examiner should note whether the patient makes mistakes and is aware of his errors. When the patient is finished, the examiner should ask him whether his remainder is correct? How does he know whether it is correct? Can he check his answer? Simple tests involving multiplication and division should be given.

It is important to note whether the patient performed these simple functions within an appropriate time span or whether his mental functioning was abnormally slow. If the latter is true, the time interval between question and answer should be noted. The examiner's impression of the patient's effort to be cooperative must also be noted.

General knowledge. The examiner must form an impression of the patient's intellectual capacity and his general knowledge. The measurement of intellectual capacity is a function of the clinical psychologist, employing tests that have been statistically validated. However, a rough estimate of the patient's intellectual capacity forms a part of the psychiatrist's mental examination. It may be estimated by testing for his general knowledge, keeping in mind the level of schooling he has completed.

Sample questions (in order of difficulty) include: What do we do with food? Name some foods. What are houses made of? Cars? Clothes? Name some rivers, mountains. Who is the President of the United States? Who was President before him, and before him? Who was the President during World War II? During World War I? Who is the governor of the state? The lieutenant-governor? For how many years is the President elected? What is the boiling point of water? What is its freezing point?

Abstract thinking. An impairment in the ability to think abstractly is found in several thought disorders. Any disorder that tends to make thinking more rigid, such as schizophrenia and some organic brain syndromes, may reveal this phenomenon. It may be tested by asking the patient the meanings of some of the more common proverbs. If asked the meaning of "Don't count your chickens before they're hatched," the normal subject answers in some general terms about the hazards inherent in drawing premature conclusions. If abstract thinking is impaired, the answer may well approximate a concrete restatement of the original proverb.

Insight. This represents the patient's ability to comprehend his current situation correctly. Does he believe himself to be ill? Does he feel the need for help? Has he come voluntarily or unwillingly to be examined? If he is in a hospital, why does he think he is there? If he does believe himself to be ill, how

does he account for the illness? To what extent does the patient evaluate himself realistically? To what degree does he understand the dynamics of his own personality and the origin of his problems?

Judgment. This refers to the individual's capacity to interpret his environment correctly and to orient his behavior in it appropriately. The psychiatrist wants to know how the patient has been functioning in school or at work, and whether he has been exercising prudence in these areas and in his family relationships.

Reliability. This refers to the examiner's impression of the patient's veracity or capacity to report his situation accurately. An estimate of the patient's reliability is an important part of the case record.

Physical Examination

Every patient requires a complete physical examination, which must include a neurological examination. It is imperative that the psychiatrist recognize that somatic disorders may present themselves through behavior disturbances. This may be more obvious when the structures of the central nervous system are directly involved. Involvements outside the nervous system may range from disturbances in circulation or nutrition to toxic manifestations of infectious diseases. The list of possible causes of behavioral disturbances is extensive. Therefore, all indicated physical and laboratory examinations must be included in the diagnostic investigation.

Psychodynamic Formulation

Having elicited the psychiatric history and performed the necessary physical and mental examinations, the psychiatrist must then attempt an amalgamation of the knowledge he has acquired. This section of his psychiatric work-up attempts to answer the questions: How did the patient become the person he is today? What were the environmental and genetic influences that shaped his personality during his early years? How did he express his fears and angers? What were his sources of pleasure and pride? How has the reality of his life circumstances produced his current situation?

This section includes an assessment of the patient's adaptive techniques and an evaluation of their effectiveness. It should attempt to explain the causes of his psychodynamic breakdown.

Diagnosis, Prognosis, and Recommendations

For psychiatric therapy to have a rational basis, it must be built on an accurate understanding of the

patient's development and life history and on the results of the physical and mental examinations. These are the elements on which an accurate diagnostic description and psychodynamic formulation are based, and they, in turn, lead to the prognosis and recommendations for appropriate therapy.

Diagnosis. In an attempt to maintain uniformity, diagnoses should adhere to the standard nomenclature of the American Psychiatric Association. Where the psychiatrist feels that this is not satisfactory, he may supplement it with whatever qualifying terms he feels apply. However, the necessity of categorizing within one nosological system can be helpful in developing a conceptual framework, particularly for students. The framework will probably be modified as the psychiatrist develops his own way of thinking with continued study and practice.

Prognosis. A prognostic statement is a part of the evaluation of the patient. It is based on the psychiatrist's understanding of his patient's assets, strengths, and adaptive weaknesses and the reality of his life situation. It is modified by the history of the patient's previous patterns of adapting to situations of stress and relative normality. Proficiency in developing prognostic skills depends on the student's insistence on including a prognosis in every work-up he does and following it up by observing the course taken by each of his patients.

Recommendations. These follow the systematic study of the patient. If the psychiatrist can understand the patient's development and the vicissitudes of his life experiences, he should be in a position to recommend an appropriate course of therapy. Alternately, there will be times when the recommendation may be for no psychiatric therapy. When psychiatric referral has been for the purpose of evaluating a patient, such a recommendation may be most helpful to the referring physician.

Suggested Cross References

For a more detailed discussion of the various symptoms mentioned here, see Linn's section on psychiatric symptoms (Section 13.1) in this area. Sections on psychological tests (Sections 12.1 and 12.2) and the role of the physical examination in psychiatric diagnosis (Section 12.4) may also be found in this area.

Chapter 12

Ancillary Data in Psychiatric Assessment

12.1 PSYCHOLOGICAL TESTING OF INTELLIGENCE AND PERSONALITY

ZYGMUNT A. PIOTROWSKI, PH.D.

Test construct

It seems best to view psychological tests as microscopes or x-rays if one wants to grasp their significance, advantages, and limitations. Performance on psychological tests, it is assumed, reflects certain selected performances in real life. Another assumption is that differences in test performance correspond to differences in life performances, other conditions being equal—be they differences among many individuals or differences among several test examinations of the same individual.

Different tests yield information about different psychological aspects. Tests of potential intellectual capacity differ from tests of intellectual efficiency. Tests of acquired mental skills differ from tests of ability to apply acquired skills to the solution of new tasks. Tests often give information not accessible in direct interviewing because it is not always possible to differentiate adequately between the level of highest potential capacity and the level of actual effective functioning. Thus, many ineffectual psychotics perform surprisingly well on some tests of abstract reasoning; less frequently, an apparently imaginative patient does poorly on tests of imagination as well as on tests of reasoning. Some patients, after brain concussion, appear clinically to reason logically and on a superior intellectual level but reveal a severely and consistently defective immediate memory on a variety of memory tests. A severe memory defect leads to confusion, even if the patient's verbal reasoning is superior. The norms of every standardized test enable the examiner to evaluate any individual's test performance and its implications for performance in life far more realistically than a non-standardized interview can. However, the increased precision that testing provides is not always necessary for the understanding or treatment of diseases.

Reliability and validity are indispensable concepts in psychological testing. A test is reliable when re-

peated applications of the test yield the same results, provided the tested individual or mental function has not changed significantly between the testing periods. Reliability is the self-consistency of a test and depends primarily on the length of the test (longer tests tend to be more reliable) and the spread of test scores in the group of subjects measured (the greater the spread, the greater the reliability). Whereas reliability refers to how dependably a test measures what it measures, validity refers to how well the test measures what it is supposed to measure. A test can be reliable without being valid, that is, without having any useful application. It may have no significant correlation with any important empirical variable of emotions, conduct, reasoning, etc. A test cannot be valid unless it is reliable. It can have different degrees of validity when it is correlated in various degrees with different variables or personality aspects. For example, tests of emotional attitudes are more valid as indicators of internal emotional attitudes than of overt behavior in emotionally stimulating social situations; and verbal tests of intelligence reveal with higher validity potential reasoning power than effective handling of reasoning problems.)

Microscopic or x-ray evidence is always limited, and this limitation applies to psychological tests. Sometimes a test is easily and validly interpreted, and at other times its relevance is doubtful or incomplete unless it is integrated with other data. The degree of reliability of different tests and of different uses of the same tests varies. The application and interpretation of some tests require long and difficult training; in other tests, they are relatively simple. The projective personality tests are among the most difficult to interpret; and consequently, in the present stage of development, it is still true that the skill of the interpreter of these tests is no less important than the tests themselves. The paper and pencil questionnaires (the personality inventories) eliminate the influence of the examiner almost completely, both in the administration and in the interpretation of the subject's responses, if norms are available. The application of intelligence tests requires sound training and care which is all the more true of projective tests.

Intelligence Tests

General concepts

Intelligence. Intelligence is a controversial concept. The most widely accepted definition of intelligence is: the capacity to solve new problems by means of rea-

soning. It involves an understanding of the relevant issues in new tasks and thinking of successful or satisfactory solutions to the tasks. The emphasis on novelty of the tasks serves the purpose of differentiating acts of intelligence from memory feats, although it is realized that memory has a role in reasoning. In tests of intelligence, reasoning is stressed, not concrete performances, because manual performances are easily influenced by transient emotional stress and by training. Moreover, it is useful to have a measure of potential intelligence in order to have an estimate of what kind of work the individual could be doing. This potential power cannot be measured directly, but it may be inferred from the results.

Factors to be kept constant. Since test results depend, at least in part, on training (including relevant experiences of any kind), interest, and effort as well as on intellectual capacity, it is important that training, interest, and effort be kept constant so that differences in intelligence can be measured in terms of differences in test scores. This requirement is met by (1) constructing tests measuring a great variety of mental tasks, (2) limiting the unqualified application of test norms to subjects who had at least the same educational opportunity as those whose test performance provided the norms, and (3) making certain that the subject was sufficiently motivated in answering the test questions.

The psychologist's role in ascertaining interest and effort is essential and can be difficult in the case of young children and withdrawn psychotics. Depression, which always affects test performance unfavorably, escapes detection easily. Test results should not be accepted as valid unless a qualified psychologist feels confident that all requirements of reliable testing have been met.

Intellectual level. The intellectual level, determined by a reliable examination with a sound test after the 4th year of life (provided there is no speech disorder and no disease of the central nervous system), is one of the most lasting and most important human traits. Individuals with adequate intelligence may not achieve what they are capable of for a variety of reasons, but no matter how hard a person with insufficient intelligence tries, he cannot achieve what is beyond his capacity. Time and again claims are made and alleged proofs are offered that intellectual capacity (the I.Q.) can be raised by proper training. But analysis shows that the improvement in the I.Q. on reexamination is spurious because motivation and cooperation greatly differed on both examinations.

Individual versus group tests. When an individually administered test differs from a group test, the result of the group test should be disregarded. Individual examinations are far more reliable than group tests because of the opportunity the examiner has during the individual test to estimate and control the degree of cooperation, a matter of particular importance in the study of mental patients.

Emotional factors and brain disorders. Intelligence tests measure reasoning about impersonal and rational mental problems, the solution of which may require prolonged and conscious concentration. Different types of tests differ in their resistance to emotional factors and are affected differently by different types of brain lesions. With the exception of patients with lesions in the speech areas of their dominant cerebral hemisphere, the ability to define words resists functional and organic brain disorders best, and vocabulary test scores can be accepted as approximate measures of premorbid intellectual ability.

As more and more is learned about specific test result patterns in different kinds of brain disorders, specific conclusions replace broad generalizations. In general, the effect of emotional stress or of functional and organic brain disorders on test results increases with the degree to which the test is an "open eye test," that is, the degree to which it involves visual-motor perception and coordination, speed, and adaptation to a new task, especially if the task is of no perceptible significance to the patient in his daily life. Words, speech, and communication are always important. "Closed eye tests" that can be answered quickly and briefly on the basis of long acquired and well tested verbal knowledge without the use of the hands or the senses (except hearing) resist deterioration best. This is well illustrated by the significantly greater variability of scores on nonverbal tests, particularly in the case of very disturbed mental patients.

Measuring and scoring I. Q. Modern psychological testing began in the last decade of the 19th century when Alfred Binet developed the first intelligence scale to separate the mentally defective (who were to be given special education) from the rest of the children (whose school progress was to be speeded up). Realizing that intellectual capacity cannot be measured directly and that test scores are a function of training and practical experience as well as of intellectual capacity, Binet eliminated the effect of differences in training and experience by constructing the first battery of diverse tests, assuming that training and experience would be approximately the same for all children on a test battery, even when they differed on the individual tests of the battery.

Binet also introduced the concept of the mental age (MA), which is the average intellectual level of a particular age. The intelligence quotient (I.Q.) is the ratio of MA over CA (chronological age) multiplied by 100 to do away with the decimal point. When chronological and mental ages are equal, the I.Q. is 100, that is, average. Since it is impossible to measure increments of intellectual power past the age of 15 by available intelligence tests, the highest divisor in the I. Q. formula is 15.

Another way of expressing the relative standing of an individual within his group is by percentile. The higher the percentile, the higher his rank within a group. For example, if an individual is at the 80th per-

centile level, he exceeds 80 per cent of the group in the trait measured and is exceeded by the remaining 20 per cent. An I.Q. of 100 corresponds to the 50th percentile in intellectual ability for the general population. The intellectually lowest per cent are usually classified as mentally defective.

Purposes. The reason for intelligence testing is to ascertain the role the intellectual level may play in the difficulties the subject experiences or to make educational or occupational plans for the future. Nontest estimates of intellectual capacity can be difficult, especially if the patient's education has been irregular or if he is inhibited and tense. The level of intellectual capacity has a definite influence on symptoms and the psychotherapeutic process.

Individual tests. The Binet test battery was revised and enlarged by Lewis Terman and published in this country in 1916. Two newly revised and greatly enlarged parallel batteries, L and M, of the 1916 tests were published by Terman and Merrill in 1937. The new revisions extend from the mental age of 2 years to the highest adult intellectual level.

These tests have been largely displaced in clinical practice by the Wechsler Adult Intelligence Scale (WAIS), published in 1939 and revised in 1955, and the Wechsler Intelligence Scale for Children (WISC), published in 1949. One reason for the displacement is the difference in the content of many of the tests. The WAIS consists of tests of interest to adults. The Binet is of primary interest to children. However, the chief reason for preferring the WAIS and the WISC over the Terman tests is that considerable time is saved in administering the WAIS and the WISC. This saving is made at some cost in accuracy. Both the WAIS and the WISC are less discriminating in the youngest and oldest subject groups, and even among the most and least intelligent at any age level, than are the 1937 Terman tests. The latter are more accurate as measures of mental deficiency.

The Terman revisions of the Binet, the WAIS, and the WISC are all individual intelligence tests; that is, they are administered to one person at a time, giving the examiner an opportunity to control cooperation and other behavioral patterns.

Wechsler Adult Intelligence Scale (WAIS) (This is an intelligence test for adults and adolescents of both sexes from the age of 16 up. The scale is designed for individual administration and consists of six verbal and five nonverbal tests. Norms are provided for each of the tests, for the verbal test group, for the nonverbal test group, and for the entire scale. The order in which these single tests are given is not important.

Three of the 11 tests give results that correlate very highly with the entire scale. They are verbal and include the test of general information, the similarities test (a test of logical hierarchy), and comprehension questions (chiefly a test of social intelligence). The similarities test measures a basic function of

abstract intelligence, subsuming two specific terms under their appropriate generic term: for example, orange and banana are fruit, praise and punishment are methods of correction. The comprehension questions call for answers regarding matters of social importance, such as, "Why should people pay taxes?" and "Why are people who are born deaf usually unable to talk?"

One of the verbal tests consists of arithmetical problems. Results on this test are influenced considerably by training and experience. The fifth verbal test is repeating digits forward and backward. Strictly speaking, this is not an intelligence test but one of immediate recall. Performance on this test is considerably affected by mood. People who are greatly worried by emotional problems are, as a rule, too preoccupied to do well on this test. On the other hand, some detached schizophrenics can do remarkably well and even some brain disorder patients without distinct memory defect can repeat long series of digits. The vocabulary test calls for defining single words. It is a good test, but it requires more time than the others. Schizophrenics who have primary thought disturbances often score poorly on the similarities or comprehension questions.

Three of the nonverbal tests—the digit symbol (placing geometric symbols in squares beneath digits according to a key), the object assembly (resembling jigsaw puzzles), and the colored block designs (imitating, with colored blocks, designs presented on a printed card)—are particularly sensitive to brain damage. The picture completion and picture arrangement tests complete the list of nonverbal tests.

Although David Wechsler, the originator of WAIS, suggested that the I. Q. computed on the entire scale be used as an indication of intellectual capacity, it seems advisable to use only the verbal test performance (excluding repeating digits) in the calculation of the I. Q. because performance on the verbal tests is much less variable than that on the nonverbal tests and because verbal tests resist the effects of emotional tension, psychosis, and brain disease more effectively than do nonverbal tests, unless there is damage to the speech areas of the dominant cerebral hemisphere. Performance on nonverbal tests varies noticeably with mood disturbances in schizophrenia, but performance on verbal tests is relatively stable. A subject rarely introduces idiosyncrasies into his intelligence test responses that would throw light on his emotional attitudes.

A subject's I. Q. score indicates the degree of deviation of his intellectual capacity from the average. In this lies its importance. By general agreement, an I. Q. of 100 has been selected to denote average intellectual capacity on all intelligence scales, but the tests differ somewhat in the probability of obtaining I. Q. scores differing from 100. Therefore, I. Q. scores are not directly comparable unless they are 100 or near 100. On the WAIS, the middle 50 per cent of the adult and adolescent population (there are no sex differences) obtain I. Q.s between 90 and 110. The lowest quarter obtain I. Q.s below 90, and the lowest 5 per cent obtain I. Q.s of 75 or less. Analogously, the upper quarter obtain I. Q.s over 110, and the highest 5 per cent obtain I. Q.s of 125 and over.

Group tests. These tests are so named because they are given to many subjects at the same time, although they can also be administered individually. The great-

est users of them are schools and the armed services. Being paper and pencil tests, they nearly always require good reading and thus are unreliable with poor readers. They are speed rather than power tests. They rely on questions where the answer is usually a choice among alternatives (multiple choice). They are economical and convenient but much less reliable and valid than individual tests. It is particularly inadvisable to attempt predictions in the case of emotional disturbance because transitory emotional upsets interfere with speed of reading and responding and with grasp of printed questions. Motivation during mass testing leaves much to be desired in many individuals. It is preferable to give an abbreviated individual test rather than a group test to the mentally disturbed.

Among the widely known group verbal tests are the American Council on Education Psychological Examination (ACE) for college freshmen, the Cooperative School and College Ability Tests (SCAT) for grades 4 to 14, the Lorge-Thorndike intelligence tests for grades 1 to 12, the Otis Quick-Scoring Mental Ability Tests for grades 1 to 16, and the Concept Mastery Test for undergraduate and graduate college students.

Personality Tests

Personality. Definitions of personality are numerous. They rarely exclude one another logically, but they emphasize different aspects of the concept. The most frequent reason for their multitude is the inclusion in the definition of not only a description of human behavior but also references to causal factors, confirmed or hypothetical. Since similarity of behavior does not always imply similarity of motivation, internal psychological attitudes that escape direct visual inspection must be included in the concept of personality.

A purely psychological definition of personality—one that omits physical, physiological, sociocultural, biographical, and other factors (relevant as these are in shaping personality) but that is a good working definition and is accessible to clinical observation and psychological test measurements—is the following: *personality is the role the individual plays in interhuman relationships when he feels his vitally personal matters are involved, the term "role" connoting not only overt behavior (conscious and unconscious) but also internal attitudes, action tendencies, and inhibitions (conscious and unconscious).*

Projective personality tests. The word "projection" in the term "projective personality tests" should be taken in its basic psychological meaning. These tests are concerned with visual images, elicited by and externalized on the ambiguous test stimuli and thus made objects in space.

It is frequently thought that the word "projection" should be taken in its specific Freudian meaning, which limits the process of psychological projection to traits (action tendencies, emotional attitudes, instinctual drives, intellectual processes, etc.) that the projecting individual represses in himself because they

cause him anxiety when he becomes aware of them and that he, denying them in himself, unconsciously ascribes to others when he cannot repress them completely. The fact that every examination with any projective test reveals traits of which the subject is aware, of which he approves, and which he does not hide, as well as some which cause him anxiety and some others of which he is unaware, proves that the Freudian concept of projection is too narrow a theoretical base for the modern projective tests of personality. Besides, there is room and need for a theory of the tests (for an explanation of how and why the tests reveal what they do) and for a theory of personality (for an explanation of how and why people become what they are). Freud's theory of projection is just one personality theory.

In projective personality tests, the subject projects himself by making something definite out of an indefinite sense datum or relatively ambiguous stimulus. Thus, everything that is definite in his responses reflects the subject's habitual ways of reacting. These modes of reaction are never the same in all details in any two people or in any two examinations of the same person. But no adult ever changes his personality completely, except the relatively few who markedly deteriorate because of a severe organic brain disease. Two or more Rorschach test records of the same individual, taken even years apart, hardly ever differ enough to prevent correct matching in experiments that consist of selecting the record of an individual from among the records of 20 or more subjects, using another test record of that individual as a clue.

Assumptions. The following assumptions provide a partial basis for a theory of projective personality tests.

Selection. There is no perception without selection, and the process of selection is a function of personality. This is the broadest principle underlying the tests. Selection is not a superficial or accidental process; it reflects significant life interests, the intensity and quality of emotions, fears and anxiety, physical and mental strength, and degree of activity. The degree of spontaneous activity determines both perceptions and attitudes toward the world. It is through action that we verify the existence of an object and discover its full significance for us. The nervous system is active not only in receiving impressions but also in reacting to them, and selection plays a role in both reception and reaction. Selection is inevitable because of the inability to perceive and react to all potential stimuli. *What matters and how much it matters are functions of personality.* The primary function of selective perception is to facilitate action, sometimes to start action, but always to aid the acting organism.

Visual imagery. Visual imagery aids our orientation in reality much more than does the imagery of any other sense. Rorschach postulated that even the form aspects of visual percepts (visual images projected on the stimulus cards) correspond to significant personality traits. Sight is the most active, most highly organized, and most informative of our senses. It is also the most important sense phylogenetically.

Ambiguity of stimuli. This is what makes genuine self-expression possible. The visual stimuli can be considered ambiguous when they meet the following requirements: (1) They elicit a great number of different percepts from different people looking at them. (2) Each individual produces a limited number of percepts. (3) The set of percepts produced by one individual differs from those of others to a maximal degree. (4) Each in-

dividual's set of percepts varies concomitantly with his personality changes. (5) The information contained in the percepts is of a satisfactory degree of validity no matter by whom produced. The freedom the subject has in the selection of the areas he interprets and in the manner he interprets assures freedom of self-expression.

Conscious effort. The weaker the conscious effort, the greater the freedom of self-expression. The projective tests differ a great deal among themselves in the amount of conscious effort required to answer them. Drawing human figures and other objects, answering questions, and completing sentences in writing require more effort than freely associating to inkblots or even making up stories about pictures, although the latter limits the imagination far more than do the more indeterminate inkblots. The amount of useful and valid information obtained decreases as the amount of effort in answering the test increases. Any definite objective task that demands voluntary and conscious control, be it ever so small, places some limitation on spontaneous self-expression.

Directions. Absence of specific directions facilitates self-expression. When the subject can determine the nature of his task as well as his response to a given task, his freedom of self-expression is greatest. The projective tests differ a great deal in this respect. The inkblot test permits the greatest freedom in this respect because it does not demand any consistency, objectivity, or rationality. The subject can produce successive responses of very different types, varying in significance, without feeling any tension or being aware of any internal inconsistency or irrationality. When making up stories about pictures, the demand for consistency is much greater, and the subject unwittingly follows the rules of rationality and objectivity, since the stimuli themselves, pictures of real people, suggest that the stories be in some relation to the world or to objective human relationships as they are known to the individual taking the test. This is still more the case with the Minnesota Multiphasic Personality Inventory. After all, the sense of reality works automatically except in psychotics severely handicapped by their illness.

Ignorance. Anxiety is alleviated through ignorance of what one discloses about himself. Unless the subject knows the projective techniques well and makes a successful effort to give responses that, interpreted according to standard test rules, create an impression deliberately intended by him, the test responses are reliable. The more the test stimuli and the interpretation of them by the subject absorb the subject's genuine involuntary attention, the freer and more reliable is his test performance. Nearly all people enjoy the free play of their visual associations and do not think about the significance these associations may have. This attitude of ignorance and unconcern, most easily sustained on the Rorschach and hardest to sustain on personality inventories, keeps the subject willing, consciously and unconsciously, to cooperate. Being unaware of what one discloses seems to be crucial for the validity of the tests if they are to give information not readily available through other sources. Awareness of what one reveals arouses anxiety and ambivalence easily; it alerts the mechanisms of disguise and displacement.

Creative imagination. This faculty facilitates the expression of specific personality traits. At least some degree of creativeness is necessary to give meaning to inkblots and pictures of people, to draw, and to complete unfinished sentences. Very little, if any, creativeness is needed to answer questionnaires. When the subject does not know by what standards his responses will be evaluated, he is not restrained in his freedom of associations by self-criticism and is more creative than in a state of critical self-evaluation. The significance of this assumption is illustrated by the fact that original—that is, extremely rare—and particularly unique interpretations always disclose something very important about the creators of these interpretations, even when the examiner does not know what it is they reveal. The drive they reveal plays a great role and is usually

conscious to the individual, even when he does not know he has revealed it in his response.

Persistence. The persistent and lasting test aspects reflect the persistent and lasting personality traits that constitute the basic structure of personality, assuring continuity and assimilation of experiences, stability, learning, and control over self and environment. When subjects are retested, a comparison of the easily changeable aspects of the test responses with those that change slowly or little is necessary before a decision can be made as to the nature and degree of personality change. This assumption implies that the degree and nature of the test changes correspond to the degree and nature of personality changes. This assumption, necessary for the validity of the tests, is confirmed best in the case of the revised Rorschach and least in the case of personality inventories.

Anxiety and difficulties. These stimulate imagination more than do pleasure and contentment. All projective techniques seem to reveal trouble, inner conflicts, and tension much more readily than contentment, happiness, and success. This is not true of personality inventories, but these techniques are not projective tests. Among the reasons for the ease with which projective tests sample trouble and worry is their functioning like psychological microscopes: all surfaces look rougher under a microscope than when viewed with the naked eye. Sometimes the stimulus favors dysphoric reactions (for example, many Thematic Apperception Test pictures). Another relevant reason is that an important function of imagination and thinking about sense data is the function of warding off possible trouble and preparing for handling trouble. An attitude of care-free self-confidence seems to stimulate thinking and imagination much less than does anxiety. States of gratifying relaxation are states of diminished readiness for both mental and physical action. An unanxious, well adjusted person does not linger in his own past because he does not have much unfinished psychological business that stirs unpleasant memories. This assumption explains, in part, why projective tests are valuable in psychopathology.

Parallelism. The handling of projective test stimuli parallels the handling of personally vital interhuman relationships; the latter includes not only overt behavior toward others but also internal attitudes, not accessible to direct observation, related to the handling of significant interhuman relationships. Unless the internal attitudes are considered, the assumed parallelism cannot be demonstrated. In fact, projective personality tests reveal the inner man more fully than the outer man. Moreover, only results of a full analysis of the tests can parallel the role the individual plays in personally vital interhuman relationships. When the analysis is limited to the verbal narrative or anecdotal content and the nontest psychosocial behavior of the individual is limited to overt and directly observable action, no parallelism can be expected because pertinent aspects of test responses and actual living are left out of the comparison. The Rorschach test does not even allow a direct comparison between verbal test content and overt psychosocial conduct; it would be absurd to view the subject's responses about animals, inanimate objects, and many other objects as literal descriptions of his own social behavior. It requires a special dictionary to translate the subject's manner of handling the test stimuli into ways in which he deals with others, internally and externally. The translation from test behavior to life behavior is almost direct and simple in the case of some test components, and it is indirect and complex in the case of other test reactions. Projective tests differ in the degrees to which they meet the requirements of the parallelism assumption. Their degrees of validity differ accordingly.

Principles. Not all reactions to any psychobiological test, including projective personality tests, are of equal significance; they vary in degree of validity and importance. Some are of little if any significance, some may have an unknown meaning, and some are

very valuable. There are two formal principles that aid in the sorting out of projective test responses and even of dream and interview material. They are named the verb versus noun principle and the same figure versus other figure principle.

Verb versus noun principle. It is easier to deflect an action tendency toward another object or person than to suppress it. We love our desires more than the objects of our desires. People change the objects more readily than the desires themselves. Since drives are expressed in verbs and objects of drives are expressed in nouns, verbs are much more likely to be undisguised and valid at face value than are nouns, which frequently fail to indicate the primary or genuinely intended object. Changing of imaginary human figures is easy in dreams and in projective personality tests, especially in interpretations of inkblots. On the other hand, imagined drives need not be changed because the dreamer or tested subject can make them appear innocuous to himself in his own imagination: he can make the wishes come true and the dangers safe.

The easiest way to calm anxiety while engaging in spontaneous visual imagery is to have one's unacceptable, tension-producing drives carried out in imagination by characters unlike oneself or to direct them at characters unlike the real persons for whom they are actually intended, though the subject may not be aware of it. Nouns connoting human beings, then, are likely to be more frequently distorted than verbs connoting social interactions. The nature of the test stimuli (blots, pictures) facilitates this difference in distortion. The verbs can be classified into groups according to whether they indicate movement toward or away from others, movements overcoming or surrendering to the pull of gravity, free versus inhibited movement, active versus passive movement, successful versus failing actions, lonely versus social activities, etc. The difference in the degree to which drives and their objects are distorted must be remembered in studies of validity; otherwise, validation of projective tests misses its purpose.

Same figure (SF) versus other figure (OF) principle. The SF is a test figure of the same sex, approximately the same age, etc., as the subject; the OF differs from the subject in all these traits. The principle states that drives ascribed to the OF are less likely to be manifested in overt behavior than those attributed to the SF. In other words, drives acceptable to the subject tend to be projected onto the SF, the unacceptable ones are projected onto the OF. The meaning of the difference between same sex and other sex test figures applies also, though in a lesser degree, to the difference between same age and other age, human and nonhuman test figures, and to the difference between statements made using the first person singular pronoun and the third person singular pronoun.

Since it is most difficult to say whether an action tendency elicited by a test is conscious or unconscious, the terms "acceptable" and "unacceptable" are pre-

ferred. The principle implies that drives and other attributes ascribed to the OF are at least partly inhibited and cause anxiety when the subject becomes conscious of them or tries to carry them out in action. Special favorable conditions (strong motivation, good rationalization) are needed to actuate the unacceptable drives.

What a subject says about the OF may also divulge his views of real people of the opposite sex, different age, etc. A subject who is anxious about his weakness may reveal his feeling by ascribing weakness to children in his test performance. Similarly, fear of old age and death can be expressed by creating old and sickly test figures. Knowledge of ourselves and knowledge of others are interdependent, and the greater the inhibitions (the unacceptability of one's own drives), the greater the likelihood of feeling uncomfortable with others. As inhibition increases, the likelihood of preconceived and distorted ideas about others as well as oneself also increases.

Inferences from the OF regarding the subject's unacceptable drives seem to be more frequently confirmed than those concerning the manner in which the subject thinks other people relate to him. The SF-OF principle can be applied to Rorschach human movements, Thematic Apperception Test characters, free drawings of males and females, and even dream figures.

Rorschach perceptanalytic test. (The purpose of the Rorschach test is to deduce personality traits of individuals from an analysis of spontaneously produced visual images stimulated by indeterminate stimuli, a set of inkblots. A stimulus is called indeterminate when it can be interpreted in a variety of ways with equal plausibility.)

Leonardo da Vinci was the first to use indeterminate forms to stimulate creative imagination and to test future painters. Alfred Binet, in 1895, revived the use of inkblots as a test of individual differences, but he limited their scope, calling them a test of passive imagination. George V. Dearborn, in 1898, was the first one to realize that inkblot responses can reveal complex traits reflecting social relationships and the degree of emotional stability.

It is doubtful that Rorschach knew about the work of his predecessors. His greatest achievement was the discovery that not only the verbal content of the responses but also the formal aspects of the visual images contribute important information about distinct personality traits. Although many diverse responses to the blots are obtained, the fact that each individual limits his personal reactions to relatively few responses contributes greatly to the reliability and validity of the technique. Rorschach records of the same individual are very similar, regardless of the number of examinations, unless the personality changed as a result of a psychosis or brain damage.

Description. The Rorschach test consists of ten symmetrical inkblots, printed on a white background and mounted on 6½-by 9½-inch cardboards (see, for example, Figure 1). Five of the blots are in varying shades of gray, two are red and gray, and three are multicolored. The subject can view the blots in any position, but he is not allowed to hold them at a distance greater than arm's length. The examination con-

sists of the performance proper, during which the free visual images are obtained, and a subsequent inquiry. The purpose of the inquiry is to remove any doubts the examiner may have concerning the images produced by the subject and thus to assure reliable scoring.

Scoring. The main scores are divided into four categories. The area scores indicate the portion of the blot interpreted: the whole blot, a frequently selected detail, a small and rare detail, or the white areas. The next category, the determinants, includes movement, color, shading, and form responses. The third covers content: humans, animals, anatomy, botany, inanimate objects, etc. The fourth category contains components indicating the degree of accuracy with which the images fit their respective blot areas. There are good, poor, and indeterminate fits. The subject is permitted freedom of association. Encouragement to elaborate on some of the responses does not invalidate the test, so long as the examiner makes no direct suggestions.

The scores or components help in the analysis of the test records by providing a summary. The *W* or whole responses cover whole blots and are positively associated with a genuine readiness to achieve something noteworthy through personal efforts: no *W*, no drive; many *W*, marked drive. However, the quality of the drive and the results depend on a number of other traits besides genuine readiness to achieve something difficult and constructive.

The *D* components stand for details or parts of blots that are often selected for interpretation. The *D* are the most frequent area components, and a marked reduction of their number suggests poor judgment. The *d* scores cover small and rarely selected blot details. When increased in number, they indicate a tendency to preoccupy oneself with tiny, disparate details that, put together, do not amount to much. The main implication of increased numbers of *d* is alleviation of anxiety through keeping oneself busy with small and unimportant tasks.

Increased white space responses or *S* (more than two) are associated with constitutional strength, habitual oppositional attitudes, and a tendency to change decisions, each time with a feeling of finality. Psychotics with *S* may be difficult to handle, but they resist the effects of psychoses better.

The *M* or human movement responses reveal deep seated action tendencies that press for outward manifestation whenever there is an opportunity. The *FM* components symbolize animal movement, and the *m* scores symbolize movement of inanimate objects. The *m* scores seem to reveal attitudes the subject considers desirable but beyond his psychological means. The *FM* responses tend to influence overt behavior in states of diminished consciousness, such as great fatigue, intoxication, and twilight states.

The color responses are divided into three components: *FC* or form-color, *CF* or color-form, and *C* or

FIGURE 1. Plate I of the Rorschach Test. (Reprinted by permission, Hans Huber Medical Publisher, Berne.)

formless. color. All these *CR* (color responses) disclose emotional attitudes regarding others. As the form element in the *CR* increases, the consideration for others increases also, but the intensity of emotions weakens. Being a late addition, the shading and dark color responses have been given a variety of symbols and meanings in Rorschach literature. The light shading responses or *cR* are related to alleviating anxiety through a decrease of motor activity (increased motor control); the dark or black color responses the *cR*, are associated with alleviation of anxiety through counterphobic increases of motor activity.

The *F* or form responses are, as a rule, the most frequent in an individual test record. If not, the individual tends to take too many things personally. The *F* scores represent action tendencies or attitudes that are least personal, relatively most socialized and rational. A separate component is the percentage of sharply perceived forms; when this drops below 70 per cent, the capacity for prolonged and conscious control over thought processes is strikingly decreased. The rare people whose *F*+ percentage is 100 are intellectually meticulous, if not rigid.

Content components are indicated with abbreviations: *h*, whole human being; *hd*, human body parts; *sex*, genitals; *bt*, botany; *ntr*, nature; *bl*, blood; *obj*, inanimate objects; etc.

Since the publication of Rorschach's book in 1921, many new components have been added but are not in universal use.

Interpretation of basic life roles. The realization that an individual can act as if driven toward a definite and persistent purpose even when unaware of it is a discovery that has radically changed psychology in recent decades. Drives that change least and, when they do, change gradually are revealed by the *M* (human movement responses) of the Rorschach inkblot test. These potential behavior patterns press for overt manifestation insofar as internal and external conditions permit. They are stronger than the effects of pain and pleasure, and most of their driving power comes from the unconscious.

Three main types of *M* can be differentiated: assertive, compliant, and blocked. In the assertive, the

movement overcomes the pull of gravity, and the M figures expand in space, for example, "two women dancing." If this kind of assertive movement is felt to be unhampered in any way, if it is free and spontaneous both physically and mentally, a person producing such M exclusively would be described as self-confident, ready to assume responsibility for himself and frequently for others as well, having initiative, and eager to leave a mark of his personality on others.

In the compliant M, the figures give in to the force of gravity or submit to the influence of another power, reducing movement or self-controlled expansion in space, for example, "falling down," "bowing." Persons who produce exclusively compliant M lack self-confidence, look for a benevolent guide who would take the ultimate responsibility for their thoughts and actions, and suffer from having their spontaneity curtailed. The great majority of people who seek psychotherapy have compliant M or essentially assertive M with serious restriction of spontaneity and freedom of action in their M figures. An example of the latter is: "two men trying to lift something; it's heavy, and I doubt that they'll make it."

Patients with assertive M are easier to help psychotherapeutically than those with compliant M. Reexaminations show that the quality of the M is the last test component to change, if it changes at all. There is no more desirable M than an easily performed, spontaneous, counter-gravity activity. Patients undergoing a real character improvement move toward this ideal M in their post-treatment reexamination. Some patients undergo an apparently spontaneous movement in the opposite direction, toward compliant M or assertive M restricted in freedom and speed of expression. Such changes are usually a sign of an approaching psychotic breakdown.

The third type of M is blocked between assertion and compliance and thus discloses deep-seated and hard to change obsessive doubts whenever an important decision affecting significant human relationships must be made. The classical example is: "two men pulling in opposite directions with equal strength." Much energy is spent, but no overt movement or change is made. Such individuals have lost much of their self-confidence but have not yet surrendered to the directing and domineering influence of others. They do not know whether to trust themselves or others, to take responsibility for themselves or depend on someone else for support and guidance.

The action tendencies or life roles revealed by the M go back to early childhood, and thus the M responses throw light on patient-parent relations. Even minor variations in the content of the M seem valid and should be analyzed. No single Rorschach plate elicits, always or exclusively, information about the subject's attitude toward father or mother. However, M components in which male figures appear indicate life roles developed in living with father; M components with female figures disclose life roles developed

in living with mother. "Quarrelling women" suggests that the patient developed verbal aggressiveness while accommodating to mother. "Bowing men" points to father as responsible for the patient's compliance; it is expressed in an acceptable social form, but it is a handicap nevertheless.

People who produce M responses of different kinds are more complicated than those with but one type of M response. Since overt behavior is never a vector or average of all potential behavior patterns (we are never perfectly integrated), the presence of various types of M does not complicate life as much as might be expected, although it does cause strain. Effective doers usually have only one type of M, the assertive type as a rule. On the other hand, introspective individuals produce M scores of a large variety. The capacity for diversified M seems associated with psychological perceptiveness and intuitive understanding of others. Schizophrenics who produce many M responses do not deteriorate, and deterioration caused by brain damage results in the loss of the ability to produce M responses. Cerebral cases with M have a better insight into their condition than those without M, and thus they complain more of their handicaps. As M increases, pride appears. The main concern of the individual with many M responses is to be at peace with himself and to live up to his own standards rather than those set by others.

Interpretation of emotions regarding others.

Clinical observations and projective personality test conclusions gain in clarity and meaning when emotional attitudes regarding mainly others are separated from those regarding primarily the subject himself. These two types of emotions can vary independently of each other, especially in mental patients.

Emotions concerning others can be defined as desires to associate with or dissociate from others with the intent of continuing or discontinuing the exchange of pleasures and pains. This definition divides emotions into positive (love, affection) and negative (hate, repulsion) and defines them as desires that can be accompanied by conscious feelings of varying intensity and awareness. The first impulse of a person motivated by a negative emotion is to avoid others; it may develop into open aggression if attempts at avoidance are frustrated, as in the case of children who cannot leave their parental home. Positive emotions prompt the seeking out of others to experience pleasure through them. These promptings fail if the other does not approve of the intention and refuses to be involved. It takes more tact, persistence, and effort to gratify positive emotions than negative ones, at least in the case of the great majority of adults. One has to be trained to love successfully; hating comes much more easily. Thus, sheer human inertia explains the prevalence of dislikes.

The Rorschach measure of positive emotions is a meaningful interpretation of chromatic color areas in which appear objects or processes indicative of a se-

cure or attractive life, for example, "red apples," "canaries," "bouquet of flowers," "beautiful landscape." Negative emotions are indicated by meaningful interpretations of chromatic color areas that suggest a state of disintegration or destructive processes, for example, "blood," "ugly painting," "cross section of a human body," "burning (destructive) fire." Successful psychotherapy increases the relative number of positive color responses.

Patients without any color responses are emotionally flat; those with many color responses are frequently stimulated to seek others for pleasure or avoid others to discontinue pain or fearful emotional relations. The negative color individual dreads emotional involvement with others because he expects to suffer as a result of such involvement. He is a frightened person who can be quiet in manner and is often mistaken for an indifferent and unemotional one. In both schizophrenic and organic deterioration, there is decrease in color responses. The emotionless diencephalon lesion cases do not produce Rorschach color responses.

Signs of anxiety. Projective tests reveal anxiety in so many different ways that it is necessary to specify the types of anxiety to be meaningful. Furthermore, every Rorschach sign of anxiety simultaneously indicates the life area causing anxiety and the manner in which anxiety is experienced and alleviated.

It is important, too, for best results to differentiate between anxiety and fear. Anxiety can be defined as a dread of an impending danger, the nature and probability of which is unknown and not calculable, accompanied by tense and physically exhausting alertness, an apprehensive self-absorption that interferes with an effective and advantageous solution of reality problems, an irresolvable doubt concerning the best means of counteracting the danger and one's own capacity to meet the emergency effectively when it arises. Though similar, fear differs from anxiety in that it is a dread of a known external danger, the probability of which is approximately calculable, and against which definite, objective, and effective defense measures can be taken. Fear, unless excessive in degree and thus changing into anxiety (the excess introducing the incalculable element), mobilizes mental and physical energy. Anxiety cuts down initiative, intensifies the feeling of weakness and raises the probability of being overwhelmed and destroyed.

The classical sign of anxiety is a sudden and temporary paralysis of function. Its main Rorschach manifestation is an initial delay (measured in seconds) in the production of a meaningful interpretation of a new stimulus. Occasionally, subjects fail to give any response at all to a Rorschach plate, thus displaying the highest degree of shock. There can be other shock manifestations, such as exclamations, critical remarks, etc. The Rorschach shocks indicate neurotic ambivalence regarding the advisability of

acting in accordance with spontaneous and genuine action tendencies.

The color shock, nearly always red shock, elicited by plate II or plate VIII reveals neurotic ambivalence regarding emotional desires involving others. Color shock individuals tend to blame others for their frustrations. Dark color or dark shading shock, measured by delays in responding to plate IV or plate V, is associated with anxiety over experiencing anxious and depressive states, feelings of inferiority, and blaming oneself for one's frustrations.

The frequent sex shocks pertain primarily to male genitals (potency difficulties in males, anxiety over contact with male genitals in women) when triggered by plate VI and to female genitals (castration fear in males, anxiety over possible injury or pregnancy in females) when elicited by plate VII. Sex shocks can occur as early as the 8th year of life and apparently have the same meaning as in adults. They vary greatly in intensity and sometimes are the only shocks in the test record. Plate IX shock is a valid indicator of heterosexual intercourse anxiety. Plate III shock always means that the patient is neurotically ambivalent about being his true self and, in most cases, about whether to give in to homosexual tendencies. A plate III shock in the absence of noticeable psychosexual difficulties may signal the onset of a manifest psychosis.

If not due to inadequate preparation of the subject for the test, plate I shock (failure to see anything in it or longest initial reaction time in the record) suggests paranoid schizophrenia. Shock on plate X is rare; when there is delay, it probably means anxiety regarding ability to tackle successfully the relevant problems of the future and severe criticism of past personal achievements.

Interpreting the Rorschach plates at a rapid and even pace, for example, with all reaction times below 10 seconds, signifies absence of consciously felt anxiety. It is good and normal not to feel anxiety when there are no serious personality problems. Psychotics who react in this nonanxious way lack insight into their illness and cannot be helped psychotherapeutically. Absence of shock to a plate suggests absence of anxiety and acceptance by the subject of what he does and experiences in the area to which shock on this plate pertains. Thus absence of shock on plates VI, VII, and IX (all three) means that the individual is not anxious over his psychosexual intentions, active doings, and passive experiences, regardless of what they are. Homosexuals without sex shock do not want to change, even if they give lip service to the idea of change. An analysis of the Rorschach shocks alone gives knowledge about areas that trouble the subject and in which therapeutic help is likely to be desired and areas that cause no trouble, at least at the time of testing, and where probing is likely to be resented, thereby jeopardizing the success of therapy.

One of the main ways of alleviating anxiety is a

reduction of motor activity, partial withdrawal with attempts at making one's self inconspicuous. It is a prudent method in a tightly organized society in which records are kept on everyone and are consulted. Light shading responses—meaningful interpretations of the graduations of gray on the blots—are the most important Rorschach signs of this method. As these responses, such as "furry skin," "billowy clouds," "topographical map," increase in absolute numbers and relatively to the sum of chromatic color responses, so does the individual's ability to automatically (without conscious effort) suppress subjectively undesirable motor impulses concerning others.

The other method of alleviating anxiety consists of increasing motor activity, which results in performing an action designed to reduce anxiety by attacking the source of anxiety directly or indirectly or, less frequently, in escaping anxiety by flight (suicidal attempts). The belligerence that often characterizes dark color individuals exposes them to the danger of retaliation.

When a subject produces more than three responses each of light and dark shading, he is unpredictable in the handling of anxiety. Since he cannot alleviate anxiety in both ways at the same time, he alternates, to the bewilderment of others. The great majority of patients with many responses of both kinds are schizophrenic. Few adults (no more than one fourth) produce dark shading responses. More than three fourths of adults produce at least some light shading responses. Dark color responses can appear below the age of 3. The light shading type is very rare below the age of 7. The dark color responses are prominent in brain concussion and relatively frequent in epilepsy and delinquency. They are associated also with intermittent depressive moods that come and go and are not unwelcome; these moods differ greatly from chronic and deep depressions with psychomotor retardation.

Anxiety indicated by human movement responses appears when the subject actuates the life role contained in the response. "A man just run over by a steam roller" as a response to plate IV expresses an expectation of being destroyed by inimical forces, not necessarily physical. "A contortionist with head between his legs and a grotesque mask" as a response to plate IV suggests pathetic attempts at gaining attention and influence. Both M responses point to great inner anxiety and insecurity.

Signs of depression. Deep depressions are revealed on the Rorschach by a uniformly very slow pace of interpretation with long initial delays, lack of imagination, great reduction in movement and color responses, and sometimes even a significant drop in whole responses. Any frustration projected onto an indeterminant, ambivalent stimulus—one that could be interpreted with equal plausibility in several or more different ways—discloses depression. Handicapped or frustrated movements, such as "trying hard to climb, I doubt that they'll make it," or strenuous

movements suggests persistent depression associated with attempts at self-assertion. Producing significantly smaller numbers of test components that express interest in the world and in spontaneous personal activities points to depression. It is much more difficult to lift the depression indicated by human movements than depression indicated by uniformly long initial reaction times.

Greatly reduced numbers of whole responses (covering entire blots) signify depression, with resignation and giving up of ambitions for personal and noteworthy achievement. When there are no other signs of depression, this reduction of drive is not associated with subjectively acute depressions but with chronic depressive underactivity. In general, there is a small and gradual increase in the signs of depression with increasing age after the 4th decade.

Signs of drive for acting out. An analysis of the verbal content alone on the Rorschach results in a list of potential behavior patterns, but content alone does not suffice to predict the chances of the behavior patterns being acted out. Evidence of well controlled, goal-directed, and prolonged voluntary attention is revealed by clarity and completeness of thoughts adequately verbalized, respect for reality (making interpretations fit the test stimuli), and production of sharply conceived images. This is an important control factor, preventing overt manifestation of action tendencies that the individual may feel should be suppressed. This control, the Rorschach F+ percentage, requires conscious effort and has the limitation of all consciously maintained attitudes. After a while, fatigue sets in, and the control may cease to function. The value of a high F+ percentage (percentage of sharply perceived forms) is demonstrated by schizophrenics whose behavior in conventional social situations betrays nothing peculiar.

A better control is provided by the light shading responses, being at least equal in number to color responses. This control functions without the subject's conscious effort and is more reliable than the F+ percentage. Shading responses vary more readily than color responses and can be more easily affected by psychotherapy.

There are also negative controls, which consist of a reduction of drive. Low whole responses show reduced ambitious striving; compliant, passive or qualified, inhibited movements ("trying hard to," "about to," "getting ready to") and other signs of obsessiveness point to inhibitions and delays that serve as controls. This must be said also of shocks, slow pace of interpretation, and low numbers of color and movement responses.

In schizophrenia there is an additional negative control, a lack of integration or depersonalization (extremely difficult to evaluate, if at all, on any psychological test). Highly inhibited individuals can afford to produce disapproved, antisocial, and even bizarre

ideas because of the very small likelihood that these ideas will lead to actions.

Interpretation of symbols. Psychological symbols refer to those action tendencies affecting inter-human relationships and not to static objects. "Death" symbolizes emotional loneliness and depression; rarely does it symbolize physical destruction. "Food" means emotional hunger much more frequently than physical hunger. "Blood" symbolizes fear of close emotional ties with others and fear of mental pain rather than murderous intentions or fear of physical injury. "Eyes" always reveal great sensitivity to criticism by others and to self-criticism, but paranoia can be inferred only when the patient is a schizophrenic. High percentages of anatomy indicate fear of not having sufficiently good reasoning power and a wish for better intellectual functioning rather than symbolizing sexual activities.

It is advisable to divide content according to the formal Rorschach components with which it appears. Content in form responses is more ego-distant (further away from the core of the acting personality) than content in human movements. Form content expresses fears of the environment or wishes that can be gratified by objects in the environment. Responses like "ragged edges," "torn wings," "crushed animal," disclose fears of being overwhelmed by external dangers. They are produced mainly by schizophrenics in their most anxious early phases of psychosis and also by cases of brain damage (especially head trauma) and occasionally even by very energetic and successful normal achievers who feel they have overextended themselves.

Such an unrealistic response as seeing color where none exists, for example, "a yellow butterfly" in the completely gray plate V, is produced rarely but occurs in all diagnostic groups, even very mild neurotics. It is related to a good character trait: the deliberate and successful attempt to feel and appear serene when actually suffering from a depression. The depression of cases with color projection is frequently underestimated, which may be serious in very disturbed patients.

Content of human movement responses is very close to the ego, to the core of the acting person, and thus it is of great significance. "Knives," "scissors," "swords," and similar form responses are signs of fear of being attacked; but "two men fighting" is a sign that aggressive behavior, or at least the tendency to it, is an inherent part of the personality: the subject wants to attack.

When an activity is capable of causing intense excitement in the doer, and the repertory of overt movements necessary to carry it out is simple and limited, allowing little room for variety, responses that symbolize this activity are easily and usually validly read. This is true of physical sexual activity and acts of bodily aggression. However, the repertory of all aggressive acts is so large that even strong aggressive attitudes can escape detection in tests. It is possible to develop great skill in

interpreting correctly (as proved by subsequent clinical observations) the symbolic meaning of many responses.

Signs of sexual disturbance. Many Rorschach signs of inadequate heterosexual attitudes in males have been suggested. The signs that indicate definite sexual aversion to women and clinically noticeable tendency to homosexuality are: (1) anal responses, human or animal, male or female; (2) bisexual figures endowed by the patient with both male and female primary or secondary sex characteristics; (3) spontaneously expressed inability to decide whether a figure seen in the blot is male or female; (4) figures reclining backwards with legs at least partially raised (this correlates highly with passive homosexual tendencies in males and with desire for heterosexual intercourse in females); (5) human movement responses that are frankly sexually exhibitionistic, such as fan dancers of either sex; (6) misinterpreting the usual female figure in the center of plate I or the bottom center detail of plate VII as men or male genitalia.

It is very difficult to infer overt homosexual practices correctly. Moreover, many homosexuals produce none of the above six signs. On the other hand, "two penises, side by side" and "two men touching each other with their backsides" are valid indicators of overt homosexuality. If an area frequently interpreted as a phallus (top center grays of plate II, VI, or X) is perceived as black or as covered with dirt, guilt over homosexual activity can be inferred.

Relation to symptoms. When the human movements exceed the colors on the Rorschach, the symptoms are usually ideational, thoughts rather than actions. When the colors outnumber the movements, the symptoms are motor.

The classic obsessive-compulsive reaction on the Rorschach is to perceive the blot well, to suggest a sharply conceived form to fit the respective blot area, to note spontaneously the discrepancies between the blot shape or color and those of the imagined object, to be right about the discrepancies (which are real), and to steadfastly keep in mind both the sensation of the blot and the image of the object while comparing them with each other. The larger the absolute number of such responses, the more prominent the obsessive-compulsive symptoms. Limiting freedom of action in the human or animal movement responses indicates obsessiveness in making vital decisions. When movements and colors are about equal in number, and there is also color or dark shading shock, the character structure is likely to be obsessive-compulsive. The same uncertainty and tentativeness of responses, the same spontaneous explanation of causal and spatial relations that slow down the process of interpretation, the doubt and self-criticism, the same guarding against possibilities of misunderstanding and failure are apparent on the Thematic Apperception Test.

By contrast, the conversion hysterics are not intellectually uncertain, produce very few anatomy responses, are not concerned with the adequacy of their

test responses, but their perceptiveness, both physical and psychosocial, is limited. Patients with dark color responses are counterphobic.

Significant group differences have been found between suicidal and nonsuicidal cases in several tests. However, the effort to find significant differences between attempted and completed suicides has failed, and prediction of fatal suicides is not feasible with any accuracy. Similarly frustrating has been the search for dependable criteria of alcoholism in individual cases, although some group differences have been noted.

Absence of psychosis, presence of inner stress and anxiety, inadequate capacity for a good, automatically functioning self-control (fewer Rorschach light shading than color responses) is a frequent finding in psychosomatic cases.

Usefulness in diagnosis. The Rorschach excels all other tests as an aid in making neuropsychiatric diagnoses, although there are cases in which it fails when the clinical examination and other tests provide relevant evidence. The diagnoses most frequently missed by the Rorschach are paranoid schizophrenia and brain damage with mild mental changes. An outstanding asset of this test is the information it contributes about the manner in which the patient reacts to his sickness and the curative steps he takes to minimize the effects of the illness on his thinking and acting.

There are four different diagnostic procedures, which are not mutually exclusive, but complementary.

1. The pathognomonic procedure is limited by the relatively small number of patients with pathognomonic reactions and the small number of pathognomonic signs.

2. The most intensely studied procedure is the descriptive-statistical one, which consists of noticing the frequencies with which all scorable test components occur in various diagnostic groups. It is based on the assumption that an individual whose test record approaches the average test performance of a particular diagnostic group is likely to belong to this group. Experience shows that this approach is not very successful because the test scores obtained by members of different groups overlap too much to be helpful in individual cases and because the absolute and relative frequencies of the scored test components vary far more with the severity of the disease and the patient's reaction to it than with the specific nature of the mental illness.

3. The third diagnostic procedure is systematic. It depends on both a pattern analysis of test components (correlating them instead of taking them one at a time, noting only their frequencies) and on a theoretical assumption substantiated by decades of clinical observations and concerned with the behavior of patients struggling with mental illness. The best validated systematic approach pertains to schizophrenia. It resulted in a pattern of underactivity or withdrawal and characterizes about 30 per cent of mild or early

schizophrenia. Patients who manifest this pattern fare relatively well, without appreciable deterioration, for 3 to 5 years and should not be given intensive, insight-giving psychotherapy because the removal of the defense (underactivity) intensifies the psychotic symptoms and undermines self-control. These patients are frequently misdiagnosed as obsessive or anxious neurotics.

4. The fourth diagnostic procedure is potentially the soundest but actually the most difficult one. It requires a thorough knowledge of clinical neuropsychiatry and psychopathology and an excellent mastery of the Rorschach and other tests. It consists of deducing the patient's main personality traits from the test results and using this information as a basis for diagnostic conclusions.

The Rorschach method has a built-in test of the sense of reality that must always be evaluated in any differential diagnosis involving a possible psychosis. It is necessary to differentiate between the image produced by the patient in response to the blot and called a "percept" and the patient's elaboration, both perceptual and verbal, on the primary percept. The original percept reflects the basic condition of the patient's mind much better than does the secondary elaboration. The latter is influenced primarily by emotional attitudes and the patient's way of handling his illness. The original percept reveals the condition of the primary and basic thought processes. Thus, good images with bizarre elaborations bespeak a better mental condition and thus imply a better prognosis than do vague, limited, and confused images with normal appearing, nonconspicuous verbal elaborations.

Only schizophrenics produce pathognomonic Rorschach signs. These signs must be defined in very exact terms to be truly pathognomonic. One of them, contamination, is relatively frequent and can be defined as the unknowing fusing of two or more visual images (of shapes of objects) that cover the same blot area into one unintelligible visual image, without the patient being able to disentangle the resulting confusion. The visual images must overlap at least partially. Often when a patient's attention is drawn to his contamination, he will deny having produced it. This denial does not invalidate the significance of the contamination but indicates a mild form of schizophrenia in which the patient is capable of intellectually rallying when given the opportunity. Contaminations retain their diagnostic significance, even if it is obvious that emotional strain is partly responsible for the content of the response. Children below the mental age of 8 years produce pseudocontaminations, a confusion of color and form (not several forms) with a pleasing content, for example, "flags in the sky" (blue in plate VIII), the color of the area suggesting the sky, and the form suggesting the flags. The content of the pseudocontamination is part of normal experience, but the content of a genuine contamination is likely to be

peculiar, for instance, "liver of a statesman," "female butterfly."

The second most frequent pathognomonic sign of schizophrenia is the inconstant percept of variable dimness. This consists of placing securely only part of the visual image on the blot and having difficulty in delineating the rest of it, leaving it in a dim and variable state. For example, a patient had no difficulty in locating an animal's head in the upper half of the right gray area of plate II, but he was puzzled as to how much of the animal's body he saw—that is, how much of the blot area was included in his own response.

A third pathognomonic is the use of an indeterminate visual image. The patient is not sure what he imagines. His image is very vague, but his words sound definite. An extreme example is: "This is a prehistoric creature which never existed and of which nobody knows anything." The patient simultaneously affirmed and denied his image. A similar response, given earnestly, is "half of nothing." To be pathognomonic, the response must be given in earnest.

One type of response, almost pathognomonic, expresses the schizophrenic's emotional ambivalence, such as, "two friends, toasting each other and fighting; their heads are bloody." Here love and hate are entwined in one intimate relationship. The experience of emotional ambivalence is not limited to schizophrenics, but schizophrenics are almost the only subjects who express it in a clear visual image on the Rorschach.

There are no easy rules for diagnosing all patients with high degrees of accuracy (over 80 per cent), but some experienced clinical psychologists have developed very high diagnostic skills, based in part on subtle signs difficult to quantify. It is hoped that eventually knowledge will advance and diagnostic rules will result in conclusions of high validity though based on formalized rules.

Thematic Apperception Test. The TAT, as the Thematic Apperception Test is usually called, was introduced by Dr. Henry A. Murray in 1935 as a new way of interpreting stories made up about pictures representing, among other things, human beings of both sexes and different ages, appearing alone or in a group, in various surroundings, and in various types of interaction. The interpretive system is based on a psychoanalytical theory about defenses against anxiety feelings.

Originally, the chief usefulness was seen in revealing action tendencies or drives of which the subject himself was unaware. When it became obvious that some conscious as well as some unconscious tendencies were revealed by the test, its aim was enlarged to study many personality traits, including dominant drives, emotions, neurotic defenses against anxiety, conflicts, intellectual level, work habits, active ambition, attitudes toward parental figures, and psychopathology.

In administration of the TAT, the subject is shown one picture at a time and requested to tell a complete story, that is, to describe the interactions taking place, the events leading up to these interactions, the

thoughts and feelings of the figures involved, and the outcome.

Description. Murray and his collaborators offered a set of 10 pictures for males, another set for females, and a third set for both sexes, the last set to be administered at a later date. For a number of reasons, among which a lack of time seems to be paramount, the TAT is rarely given in more than one session, and the usual number of pictures shown is about 10 (see, for example, Figure 2).

The selection of the pictures is important, since every picture teases out some specific type of information. This results not only from the differences in pictorial content but also from differences in the degree of anxiety the pictures arouse, enabling the subject to change deliberately his spontaneous, freely associated stories in order to make the desired impression on the examiner and, through him, on others. The TAT stories are more easily and more frequently changed for this reason than are the inkblot interpretations. Many subjects feel that they can predict the meaning that the examiner will attach to their TAT stories.

The use of pictures specially prepared to study specific attitudes or drives—delinquency, social relations, special occupational activities, etc.—has been disappointing. The main reason seems to be the subject's ability to guess the aim of such special examinations, and this awareness arouses anxiety or fear that, in turn, curtail the freedom of association. Thus, paratroopers retested shortly before executing a jump did not express as much fear when interpreting pictures plainly related to the dangers of parachuting as they did when interpreting pictures not related to parachuting.

Administration. The administration of the TAT is important. It is permissible to encourage subjects to give meaningful stories if they say little or are evasive. However, the examiner should not suggest to the subject any specific interpretation of a picture because the value of the test rests on spontaneous free association. Some valuable conclusions can be drawn even

FIGURE 2. Card 12 GF of the Thematic Apperception Test. (Reprinted by permission, Harvard University Press, Cambridge, Mass.)

from brief TAT stories. As a rule, mental patients who voluntarily seek help cooperate well. The problem of inadequate cooperation, evasion, and faking is more likely to occur with normal subjects made to participate in research projects or with patients involuntarily receiving psychiatric help. It is impossible to cover the same points in every examination; however, this does not lower validity; rather it raises validity.

Included in the Murray set of pictures is a blank card; the subject has to imagine a picture first and then tell a story about it. A meaningful interpretation of the blank card demands more of the subject than does interpretation of the regular picture cards. Dynamic self-expression is reduced in blank card stories. Nearly all subjects reveal wishes for happiness and relief from tension and responsibilities in their blank card stories, manifesting the universal human desire for personal security (physical, financial, emotional) and protective affection. It is a sign of severe mood disturbance and poor prognosis to produce stories of failure, violence, sickness, and fear in response to the blank card. Stories elicited by this blank card must be analyzed in a special and different manner from the other stories.

Interpretation. The regular TAT picture stories should be divided into two main parts for the purpose of teasing out information: the verbal narrative content (the events seen, in the picture) and the formal aspects (the manner of narrating). The latter include nonverbal as well as verbal reactions: pauses, doubts, qualifications, corrections, inconsistencies, remarks that do not directly bear on the story, external pictorial elements added to the visual sensations of the picture in the subject's story, and any other signs of hesitation and inhibition.

The verbal content reveals some of the subject's drives, and the formal aspects throw light on the chances of the subject expressing the drives in overt motor behavior. The neglect or misuse of the formal aspects is one of the main reasons for the unsuccessful prediction of overt behavior. By contrast, inner attitudes—drives inferred from the verbal content of the TAT regardless of the degree of inhibition—agree well with information obtained during psychotherapy, which provides the best independent information for validation of projective test results. Changes occurring during psychotherapy are also reflected in repeat TATs.

Pictures that strongly suggest ideas pertaining to a particular drive—aggressive, competitive, sexual, personal achievement, etc.—tend to elicit reaction formations and signs of inhibition; pictures weakly suggesting a particular drive elicit less distorted and more genuine attitudes toward the drive. One explanation for this finding is that nearly all the TAT pictures inspire, in almost all subjects, themes of frustration, conflict, delinquency, and other undesirable human relationships that most people prefer to avoid or, if they cannot avoid them, prefer to deny.

Age, sex, intellectual and educational level, social

class membership, cultural and racial affiliation are among the socially relevant factors that to some degree determine the content of TAT stories. These factors contribute to the personality development, but they influence even more the frankness with which genuine drives are expressed in the test. The essential point is the degree to which an individual shares the values of his group. If he does not share its values, group norms do not help the examiner understand his TAT. One would expect women to mention nurturance and abasement more frequently, aggression and sex less frequently than men do; and indeed this is the case. With increasing age, the majority of people tend to become more depressed and more realistic about social relationships; these changes also are reflected in long term reexaminations with the TAT. Autobiographies have been successfully matched with TAT stories. Many other studies, including evaluations of intellectual and educational levels have been published demonstrating the value of TAT. There were also many failures.

Value of the TAT. The reasons for disagreement regarding the value of the TAT are basically the same as those responsible for the difference in opinion regarding other projective tests. The foremost reason seems to be the failure of investigators to duplicate exactly the studies they set out to check. Another important reason is the lack of a sufficiently comprehensive, clear, and formalized basis for the interpretation of TAT results. A frequent error is predicting overt behavior solely from the verbal anecdotal content, overlooking the indices of inhibitions that must be considered in predictions of overt behavior. Among the causes of the disagreement is the ignorance of clinical psychopathology on the part of many critics of the TAT. Any measure of potential behavior is clinically valuable. Experienced clinical psychologists are in far greater agreement on the value of this test and interpretive procedures than are other investigators. The difficulty in acquiring sufficient experience and skill for satisfactory interpretations of TAT results is considerable. It is easy to learn how to administer the test well but hard to interpret it well.

The TAT set of pictures was collected primarily for patients undergoing psychotherapy in order to enable the therapist to gain greater insight into repressed drives and not to infer from them overt behavior. The purpose was to discover what troubled the inner patient. No wonder the TAT reveals liabilities much more readily than assets. Health is less dramatic than sickness. This should be kept in mind when evaluating the degree of over-all adjustment. The tendency is to underestimate the social adjustment and to overestimate inner tension.

The TAT cannot be subjected to trenchant validation until its conceptual framework is put in order. To cite an example, male undergraduates' TAT records were evaluated as to the degree of dependency. The same students were also shown slides of large and small breasts of equal degree of attractiveness as

determined by preliminary studies. The dependent males showed preference for small breasts, and this was interpreted as contradicting a psychoanalytical theory that presumably demands that dependent males prefer large breasts. It could be argued with equal if not greater plausibility that, since dependent males are likely to have castration anxiety and be ambivalent about large maternal breasts, they may prefer small breasts and would be less defensive about them. Moreover, there is a great difference between an unconscious, or a conscious but unacceptable, wish to snuggle up with Mother and a frank admission of the wish. We cannot be sure of the genuineness of the choices, and the matter certainly requires a more thorough and subtle analysis before reaching final conclusions. Validation attempts of the TAT and other projective tests suffer from such theoretical oversimplifications and disregard of psychological complexities.

Man is not what he appears but what he has done and will do. He uses words to conceal as well as to reveal. The freedom of his activities is influenced by external reality conditions, which cannot be inferred from the test, and by inner inhibitions, some of which are disclosed by the test. The presence in the test of verbal or nonverbal indicators of inhibition and of reduced freedom of mental association or physical action means that the chance of a spontaneous and complete manifestation of a drive associated with those indicators of inhibition is reduced.

Although subjects can deliberately change their spontaneous associations to the TAT for various reasons, thus lowering its validity, the examiner can counteract these changes to a considerable degree using his experience and the rapport to allay anxiety and encourage spontaneity. The proved sensitivity of the TAT to rapport can be an asset.

With increased knowledge about a patient and greater skill in meaningfully and validly relating information from a variety of sources, the examiner finds the TAT increasingly valuable. He can then make inferences that knowledge of the TAT alone does not make possible.

Interpretation of drives. A TAT record containing exclusively benign stories contains so many reaction formations of insignificant driving power that it obscures the genuine drives. Socially approved drives in the TAT are reaction formations because of the nature of the TAT pictures, which strongly favor depressive and socially disruptive themes. Drives disapproved by society and likely to lead to retaliation are much more likely to reflect genuine action tendencies. The probability of these expressed drives affecting overt social relations is high.

Drives ascribed to same sex and same age figures are apt to appear much more frequently in the subject's manifest behavior than drives ascribed to other sex and other age figures, with one apparent exception. Prepuberty children reveal as much valid information about themselves when giving stories about pictures of animals as about pictures of human figures. The Children's Apperception Test (CAT), a test analogous to the TAT but depicting animals, was especially designed for use with children. By comparison with adults, children are more frank and less inhibited, but they are also more dependent and protected. Consequently, their need for defenses is smaller.

Stories preceded by delay—a long initial reaction

time and sometimes pauses within the stories—refer to drives about which the individual is ambivalent. Ambivalence leads to inconsistency of action regarding both the frequency and degree to which the drive is manifested. A sudden change in the process of interpretation, including the level of imagination, the mood of the stories, their complexity and inner consistency, discloses great suspiciousness of others, especially if this change persists to the end of the examination. The greater the diversity of the stories and the greater the incompatibility of drives described in different picture stories, the larger is the number of unresolved problems with which the subject struggles. This is striking when the subject is passive and underactive.

An optimistic attitude, not contradicted by references to obstacles or failure, indicates a desire to accomplish even in the face of difficulties. Emphasizing the contrasting dark and light areas of the pictures is related to alleviating states of oppressive anxiety by impulsive acting out, which is almost certain to increase the subject's difficulties in dealing with others. As a rule, any spontaneous mention of hesitation, physical weakness, mental irresolution, fear, guilt, or anxiety is a sign that the drives that are the objects of hesitation seldom affect motor behavior directly.

Proof of internalization of social norms; expressed respect for law, customs, and social order; and indications of consideration for others in the TAT stories are highly correlated with refraining from antisocial behavior, even when antisocial drives appear in the TAT record. References to remorse, shame, and punishment justify the conclusion that chances of overt delinquent behavior are greatly reduced. By contrast, stories of aggression that remain unpunished and are not criticized directly or indirectly are usually produced by people who do not mind being overtly aggressive.

Drives occurring in a number of different picture stories are a result of cognitive and emotional weakness when the stories are unimaginative or neglect to account for the specific features of each picture. On the other hand, when the same basic drive is appropriately modified and elaborated on in the stories, with meaningful interpretations of the specific features of each picture in which the drive appears, and the stories are comprehensive and of good narrative quality and do not offend the requirements of consistency and respect for physical and logical laws, it means the subject is preoccupied with the drive. Such persistence presupposes strong pressure for appropriate overt behavior.

Confused and unclear thinking reduces the ability to implement drives. Spontaneous criticism of one's own process of making up the stories or of the pictures themselves is a sign of marked obsessiveness. Such criticism is much less frequent on the TAT than on the Rorschach.

The doer looks ahead. A long view into the future is

associated with active ambition and self-confidence. The longer the prospective span in the TAT stories and the more successful the outcome of the activities described therein, the greater is the chance that the individual will openly pursue the drives of his TAT. On the other hand, looking backward and mentally living in the past is associated with retrospective TAT time spans and with limited driving power for achievement. Some schizophrenics extend the past into prehistoric periods.

Interpretation of figures. A TAT figure's sex or age is rarely misrecognized. Only several of them are vague enough to make identification difficult. A misidentification of a figure that is plain to nearly all is a sign of severe personality disturbance, associated almost always with conflict over homosexuality and with psychosis. Some Congolese as recently as 30 years ago mistook the TAT human figures for animals without being psychotic. This misinterpretation may be attributed to cultural rather than psychopathological factors.

Interpretation of symbols. There are those whose training, experience, and talent make them adept in unraveling meaning hidden in symbols. If such a skill is applied to the TAT, much more information can be extracted with all the uncertainties accompanying interpretation of symbols. As long as symbolic interpretations are treated as hypotheses and as statements alerting the observer to information from other sources that can either confirm or contradict the interpretations, there can be no serious objection to them. Information extracted from symbols should complement but not substitute for information deduced with the aid of more reliable and more valid principles.

Stories about picture 1, showing a boy looking at a violin, may symbolize any pleasurable activity, including sexual activities, although the latter are not plainly stated. The same sex and other sex, same age and other age principles can be used to classify drives as ego-syntonic and ego-disturbing.

Male undergraduates were shown slides of nude women and were then retested by an attractive and affable female psychologist. The number of frank sexual ideas did not increase by comparison with a previous TAT, but the number of symbolic sexual responses did. There was a negative correlation between increase of frank and symbolic responses. When the repeat TAT was preceded by intake of alcohol, symbolic expressions decreased in favor of plain expressions. Symbolic communication implies hesitation and delay in thought and in action.

Usefulness in diagnosis. The TAT is not helpful in differential neuropsychiatric diagnosis. Patients who manifest specific psychotic signs in the TAT display even more diagnostically pertinent symptoms in clinical behavior. The TAT is less challenging to the subject's sense of reality than are the Rorschach inkblots. Consequently, the TAT rarely elicits schizophrenic and other psychotic responses, including mental changes concomitant with brain damage. The TAT indicators of psychosis do not differ from clinical signs, except that they occur more frequently in the patient's clinical behavior and with even greater frequency in the Rorschach.

These indicators of psychosis can be classified as follows: logical ambivalence (affirming and denying the same statement within the same story though in different sentences) and other indicators of incoherence and confusion; emotional ambivalence (describing the TAT figures as both hating and loving each other, as being both cruel and affectionate with each other); withdrawal from reality into a world of magical and bizarre events; stories of violence and persecution about pictures of relaxation and peace (8 GF, 9 BM, 16, 17 GF); obvious misidentification of the sex of a figure, especially if the figure is made into a mysterious person with possibly malevolent intentions; pseudo-generalizations, such as "it shows the condition of the world, humanity struggling to get out of its misery" (18 GF, the squeezing of the throat scene); heartlessness and excessive revengefulness, such as, "this girl killed her small brother because he ate her candy" (3 BM). Paranoid schizophrenia can be recognized by references to spying and abrupt as well as marked changes in the process of interpretation.

Mild psychotics very rarely reveal anything plainly psychotic in the TAT. However, typical reaction patterns, such as depressive, obsessive, hysterical, and phobic, can be frequently inferred. As a general rule, the manner in which these patterns manifest themselves in the TAT is not basically different from that observed under other conditions.

Severe depressions are indicated by a slow pace of interpretation and long initial reaction times, minimal interpretive imagination going barely beyond mere description, no references to feelings, and either no thought of the future despite encouragement or disastrous future outcomes of described activities.

Suicidal themes are signs of a less severe depression. They seem to reflect a painful anticipation of perpetual loneliness rather than of personal death. "Death," like "suicide," should be treated as a symbol and not as a description of an anticipated real event. Suicidal attempts cannot be predicted from the TAT. Death or killing in the TAT usually means permanent separation (mainly emotional), loss of control over one's fate in life or over one's own mental processes (impulsiveness in severely inhibited individuals), and suicidal thoughts. Stories in which the characters cannot successfully communicate with each other, though they try, are also associated with suicidal thoughts and depression. When the stories are dramatic and frustration and sadness are expressed in strong emotional terms, the depression is not deep. Stories in which difficulties and obstacles are conquered and stories depicting happy endings suggest a mild depression.

The most characteristic aspect of obsessiveness is irrelevant meticulousness, arguing back and forth without being able to make a definite decision or judgment. Obsessives take excessive care not to be misunderstood. They repeat themselves and explain not only their themes but also how they happened to think of them in order to dispel any impression that

they may have arrived at their interpretations of the pictures rapidly and spontaneously without preparation. The severest degrees of obsessiveness are indicated by spontaneous and plainly stated criticism of one's own test performance and its products. This happens rarely during the TAT; it occurs much more frequently during an inkblot examination.

The essential feature of hysteria is avoidance of an anxiety-producing idea or drive that presses for outward manifestation. The hysteric represses the subjective psychomotor reaction that would normally be stimulated by the idea or drive but unconsciously overreacts in inappropriate ways that attract the attention of others. He ineffectually tries to have intense emotional relationships beyond his capacity. The desire to avoid anxiety and disappointment is so strong that it leads to a degree of psychological blindness. Mention, in the test, of the inability to see or read points to hysteria. So do clearly stated sex drives that are frustrated and frank expressions of love and hate in a setting of intense but anxiety-free activity in the TAT story. Words or phrases that imply uncertainty or impossibility are rare (no obsessiveness). Feelings or actions of TAT figures engaged in a sexual or aggressive relationship are usually described clearly with the aid of many emotionally charged adjectives.

Interpretation of child-parent relationships. One of the easiest, most highly valid, and most useful applications of the TAT concerns the subject's relations with his parents. Relations between the figures in pictures 2, 6 BM, and 7 BM as they emerge from subjects' stories can be taken, in the majority of cases, as almost literal descriptions of the subjects' relationships with their parents. The relatively small degree of disguise is remarkable. It seems that, regardless of age, people never cease to feel the impact of their parents. Very old subjects, nearly all of them parents and grandparents, identify whenever possible with a TAT child figure and interpret an older figure as a parental authority. Pictures 1, 3, 5, and 12 F also contribute pertinent information but less frequently.

When the figures in 2, 6 BM, 7 BM, and 12 F are not interpreted as mothers or fathers or if they are identified as parents but described as emotionally indifferent in their relationships, the subject is seriously maladjusted. An aggressive, hostile TAT child-parent relationship reveals gross maladjustment. When TAT child-parent relations are described as affectionate, supportive, and free of conflict, the subject is likely to be emotionally stable. On the whole, psychosomatic cases express overt aggressive hostility in their TATs—but not against maternal figures.

Signs of sexual disturbance. Rather than speaking of homosexuality, for better understanding it is preferable to speak of heterosexual inadequacy, including at least partial impotence. These remarks pertain only to males, since females are much more complex in this respect.

Inadequate heterosexuality in the adult male is indicated in the TAT by stories containing odious remarks about women and expression of affectionate attraction for men. Occasionally frank homosexual themes are produced; these disclose active homosexual experiences. In the great majority of cases it is impossible to infer overt homosexual behavior, but inadequate heterosexuality can be deduced frequently and with a high degree of validity. The general principles work well. The highly valid test signs are few and identify only a small percentage of cases. Among these themes are overt homosexual activity, men killing women, misidentification of the sex of TAT figures, definite rejection of marriage, expressions of close attachment to mother, and an obvious elaboration of feminine attitudes with a simultaneous neglect of masculine attitudes. Pictures 4, 6 BM, 7 BM, 10, 12 M, 13 MF, and 18 BM are most helpful, especially peculiarly imaginative stories about 18 BM, in which three hands are placed on a slumped man.

Free drawings. It takes little time to obtain spontaneous drawings of human figures and other objects. This is a great practical asset. The information conveyed by free drawings is limited but can be very important, especially in mental patients who have serious unresolved problems. Free drawings usually reveal attitudes that are important to the patient at the time. Enduring attitudes can also be revealed at times; this is the reason for obtaining free drawings.

The attitudes are expressed through the posture or movements of the drawn figures. The usefulness of the technique is increased when the same-figure and other-figure principles are applied to it. Much slips by the censor (superego) while drawing. Degrees of rigidity and cohesion are, as a rule, well reflected in human figures.

Technique. The drawing technique is simple and can be used by both psychiatrists and psychologists. The free drawing technique consists of handing the subject a pencil and a blank sheet of paper with the request that he draw a person, a tree, a house, an animal, or any other object. The most informative free drawings, called free because they are not copies of models, are those of human figures. "All that is good or inferior in you will appear in the corresponding parts of your figures," said Leonardo da Vinci. Free drawings are created largely from unconscious motives. One cannot help but reveal through them more than one intends to. It is a common experience that it is most difficult to change them in a specifically desired manner. What the drawings reveal most clearly are body postures and body movements. Variations in these are associated with different inner attitudes.

After the subject has made a human figure drawing, the usual procedure is to ask him to draw one of the sex opposite that of the first drawn figure. Sometimes he is asked to draw also the "most unpleasant thing you can think of," his entire family, the family as animals as occurs in fables, two people (unspecified),

a tree, or a house. There is also an incomplete drawing test by Wartegg-Kinget.

The free-drawing technique, except the drawing completion test, does not use external visual stimuli. As with the TAT blank card, the individual has to create a mental image and then place it on a blank surface. The free drawings seem to represent the wished for or feared object that preoccupies the subject at the time.

Interpretation. Being a psychomotor test, the drawings involve more effort than does describing ideas that spontaneously appear in the mind. This effort limits freedom of self-expression but favors expression of certain habitual physical attitudes.

These attitudes may be transient or lasting, as is well illustrated by preoperative and postoperative drawings of patients who underwent successful surgical operations for seriously handicapping pathology. Preoperatively, the figures they drew were distorted; postoperatively, the figures were physically normal. The feeling of personality loss and lowered energy is frequently reflected in the difference between preoperative and postoperative drawings of psychotics whose frontal lobes were operated on.

Hysterics frequently draw large eyelashes. Neurotics, worried about their reputations, pay attention to details of clothing. Psychotics and cerebral cases, having far more serious problems, show much less interest in socially important physical attributes; frequently, they even show less interest in clearly indicating the sex of the figures. These patients' interest in human relationships is weak, and their desire to live up to social standards is greatly decreased. The deindividuation of brain-damaged patients with habit deterioration is plainly shown by their crude and oversimplified drawings, with no indication of sex or age, except perhaps for more hair or high heels in the drawings of women.

Patients who feel the danger of impulsive acting out draw larger drawings than subjects who are controlled because of depression, lack of energy, or lack of maturity. As the danger of acting out increases, the drawings tend to grow in size. When the figures barely fit the paper on which they are drawn and appear bloated because of inadequate graphic differentiation of body periphery, suicidal attempts are highly probable.

Transparency—body contours showing through clothing—reveals marked personality disturbances. Dark, heavy, and irregular shading, creating the impression of a smudge, is associated with a tendency to alleviate anxiety through physical and sadistic aggression.

As a rule, free drawings give the impression of plainly divulging a great many psychological attitudes. Sound knowledge of the graphic arts and of sound graphological principles help the therapist to grasp the message of free drawings. As in the case of the other projective tests, one can evaluate drawings in two different but mutually not exclusive ways: (1) a formal attempt based on reliably identifiable graphic signs

and (2) a global inspection aided by empathic insights. In experienced hands, the latter procedure works far better at the present time. It is possible to differentiate more than 100 objective graphic signs in human figure drawings, and most of the signs can be ascertained with a fair degree of reliability. Significant differences in the average number of signs between many different subject groups have been obtained. However, considerable overlap frustrates the use of signs for diagnostic purposes in borderline individual cases.

Long continuous strokes indicate perseverance at work, usually associated with obsessiveness and fear of failure and risk taking. Long continuous lines are a good prognostic sign in psychosis. Broken lines in drawings made by children are associated with poor work habits; in children they are related to poor school achievement, but they are associated with inventiveness in adults who have high intelligence and other assets. Shaded areas consisting of short, broken, and parallel lines indicate anxiety and feelings of personal inferiority.

The stance of the figures is of paramount importance. A strong, stable stance indicates self-confidence, even if the drawings contain peculiarities. It bespeaks a good prognosis in psychosis. Some figures drawn by resigned and withdrawn schizophrenics appear to float in space, though presumably standing on the ground. The greater the deviation from the physically most stable posture—one that can be maintained with ease for a long time—the greater is the inner tension and emotional instability.

Instability is associated also with deviation from the central location of the figure on the paper. Inhibition seems to be correlated with increasing moving of the figure toward the right edge, and a tendency to impulsive acting-out is correlated with moving it toward the left edge. Pushing it down is said to suggest respect for authority figures; pushing it up is said to reveal a lack of appreciation of differences in social influence.

Crude whole figures with only some facial features, absence of crotch, omissions and distortions of body are the most valid signs of great anxiety. Depression is suggested by small size, heavy lines, scarcity of details, and a dejected facial expression. Body rigidity and emotional rigidity in drawn figures are dependable signs of deep-seated rigidity in the subject, even if his conventional behavior does not show it.

When the male and female figures differ in an easily noticeable degree in nonsexual features, the other sex figure practically always looks more anxious or disturbed in some other way. Marked differences in size indicate either depression or fear of impulsive acting out, according to whether the other sex figure is smaller or larger. Depersonalization and emotional withdrawal are sometimes clearly revealed in the other sex figures drawn by incipient schizophrenics. If different from the same sex figure, the other sex figure shows what the subject wishes not to be. When the other

sex figure looks normal and contented, while the same sex figure looks odd and anxious, schizophrenia is most probable.

The condition of the drawn tree is believed to parallel roughly the subject's vivacity. A dead tree without leaves suggests emotional emptiness. A full-blown tree with many leafy branches reflects liveliness. A weeping willow suggests weakness and inability to resist others. A tree that looks like part of a defense palisade, with spearlike branches or trunk ends, points to a tendency toward sadistic physical aggression. Sometimes preoccupation with past psychological traumata can be inferred from holes or cuts in the tree trunk. The approximate period in which the trauma occurred can be deduced from the position of the deformity. The higher in the tree the deformity, the more recent is the trauma presumed to have been; and the lower the deformity, the older the trauma is believed to be.

Drawings of houses rarely add important information. They disclose, at times, how the subject would like to live, among whom, and on what scale. The feeling of security and sociability is reflected in the type of house drawn. The houses differ in friendliness, the extremes looking like barely accessible fortresses with small and high windows or like an inviting open house in which many people engage in diverse activities.

Value of free drawings. Although free drawings of human figures and other objects do not reveal as many personality aspects or as many lasting traits as the inkblots or the TAT pictures, they are very helpful as indicators of problems, nearer the surface of consciousness, that trouble the subject at the time. This renders them invaluable as an adjunct in psychotherapy. The hand usually speaks sooner than the tongue. The value of the drawings can be raised by having the subjects tell stories about their creations.

Bender-Gestalt designs. Clinical psychologists often use these easily administered designs to aid in the diagnosis of brain damage. Sometimes the designs are also used as a personality test, but the results of such an application are of low validity or, when valid, of limited scope. They can be of value in estimating the chances of impulsive acting out.

Description. Nine of Max Wertheimer's geometric designs, greatly differing from one another, constitute the Bender-Gestalt test. The designs are presented one at a time to the subject, who is instructed to copy them on a sheet of paper. Frequently, the subject is immediately asked to copy the designs from memory after he has finished copying them from models. Thus, the Bender designs can be used as a test of both visual-motor coordination and immediate visual memory.

Value. The value of these designs as a personality test is doubtful at best. Objective scores based on measurement of deviations of the copied designs from the models do not provide more or better information about personality dynamics than a global inspection,

but they decidedly are important in the detection of brain disorders.

Although not all patients with brain damage make conspicuously deviant designs, certain identifiable peculiarities, such as rotation by 45°, marked distortion, perseveration, straight lines for dots or curves, inability to reproduce the angle between two figures constituting one design, conspicuous fragmentation, indicate brain damage with a satisfactory degree of validity, with the following qualifications. In the case of children, it is important to differentiate between a lack of skill due to immaturity and a lack of skill due to brain damage. Chronic schizophrenics with personality damage and poor prognosis sometimes copy the drawings in a strikingly deviant manner. It is necessary to guard against interpreting tremulous lines and other graphic defects caused by a transient examination fear or peripheral neurological or muscular impairment as signs of central organicity. Norms, helpful in detecting brain damage, are available. The Bender-Gestalt rarely aids in other differential diagnostic problems.

Word association and sentence completion tests.

The word association is the oldest standardized personality test. C. G. Jung was the first to use this test for the discovery of neurotic conflicts. The test is easy to administer and score and takes little time, but its results are usually meager.

Description. A number of these tests require the subject to name, sometimes to write down, the first word that enters his mind when he hears the stimulus word. For several of these tests, norms are available that consist of lists of the most frequently obtained associated words. Kent and Rosanoff provided frequency tables of responses given by various neuropsychiatric patient groups to a list of 100 words. Special lists of stimulus words can be made up for special purposes: to identify tension in special areas, severe physical illness, chronic defects, sexual frustration, etc. It is relatively easy to collect normative data.

The examiner records not only the verbal response but also the time and any signs of blocking or tension. An immediate repetition of the test, which can vary from 50 to 100 words, sometimes provides additional clues when the response words differ from those obtained during the first administration. Original responses are always worth investigating.

The sentence completion test is an elaboration of the word association technique. It consists of incomplete sentences, one word or more, which the subject is requested to complete with the first words spontaneously occurring to him as he reads the unfinished sentence. These tests can be given orally, which gives the examiner an opportunity to observe the patient, or they can be given in writing to save time. The number of test items varies greatly from one form of the test to another. All these forms share many aspects, but they differ in their attempt to tap certain psychological areas, pathology, occupational problems, political and social views, leadership qualifications, etc.

Interpretation. Many sentence completion tests have few reliable norms or none at all. The interpretation is left to the skill of the examiner. Therefore, the value of these tests depends very much on the psychological acumen of the evaluator of the tests.

Other forms do have norms. The A. R. Rohde sentence completion method provides carefully collected norms for different age and sex groups. The J. B. Rottler incomplete sentence blank was designed to get an overall picture of emotional stability. The Veterans' Administration incomplete sentences test was designed to assist in therapy planning.

The sentence completion tests provide little information if one uses only the available norms for their interpretation. They provide some useful information if interpreted by very experienced clinicians who have sound knowledge of the correlations of clinical symptoms and verbal expressions. Easy to administer and evaluate, the sentence completion test is sometimes given in the hope of getting original deviant responses.

One has to know how to read well between the lines to deduce from the word association and sentence completion tests new and valuable information. Both tests are projective tests because of the indeterminateness of the stimulus. However, the indeterminateness of these stimuli is very restricted when compared with the unstructured inkblots, which elicit a much greater variety of responses than words and unfinished sentences.

Minnesota Multiphasic Personality Inventory. Known as MMPI, the Minnesota Multiphasic Personality Inventory was introduced by Starke R. Hathaway and J. Charnley McKinley in 1942. It is the most carefully constructed and investigated inventory in use today.

The projective tests, like the Rorschach and the TAT, were prompted by a desire to penetrate deeply into the personality of the individual and were created in peacetime. The questionnaires were constructed to meet the need for quick mass examinations. The first one, Robert S. Woodworth's of 1917, and the best one, Hathaway's of 1942, originated during wartime to meet the pressing needs of the military. Questionnaires are easy to administer and require little time and effort on the part of the examiner, since the subject evaluates himself. Only the scoring of the complete MMPI takes a good deal of time, unless it is done by a computer. Much of the popularity of the test can be explained by the psychology of the examiner. He does not have to make any decisions and thus has no responsibility for the results.

Description. In its present revised form the MMPI is a paper and pencil questionnaire used more widely with mental patients than any other paper and pencil personality test. It consists of 550 questions in the form of positive and negative statements pertaining to a great many personality aspects, including general health, neurology, motility, physiological functions, habits, family, sexual attitudes, religion, political attitudes, and many psychopathological items relevant to psychiatric diagnosis and treatment. There may soon be available a shorter form of the MMPI, consisting of about 100 of the most discriminating items.

The MMPI can be administered in groups, but it is usually given individually. The subject is asked to answer each item in one of three ways: "true" if he thinks the item applies to him; "false" if he thinks it does not; or, when he cannot say whether an item is true or false, by writing the appropriate answer on the test blank.

It has been discovered that some questions that did not appear to have any relation to important psychological syndromes are actually subtle and indirect signs of pathology. Most of the items are taken from clinical psychiatry (chiefly Kraepelinian). A deliberate attempt has been made to use descriptive items. No question was included for purely theoretical reasons.

The items are combined in scales. Each scale was validated by studying various psychiatric diagnostic groups to see whether the scale items truly differentiated them. The inclusion of an item in a scale depended on the results of such an investigation. There are nine psychopathological MMPI scales: hypochondriasis, depression, hysteria, psychopathic deviation, masculinity-femininity, paranoia, psychasthenia, schizophrenia, and mania.

Usefulness in diagnosis. Since the test pertains to intimate personal matters and since in many instances the subject can predict what interpretation is likely to be placed on his response, answers to the MMPI (or any questionnaire) are seldom completely frank, either because of conscious fear or unconscious defense against anxiety. The directness of the questions violates the principle of anxiety alleviation, which seems to be a condition of a frank and valid psychological self-evaluation. For this reason, the MMPI is not a dependable aid in neuropsychiatric diagnoses, especially in borderline cases, when a diagnostic aid is most helpful.

In general, the MMPI profiles formed by the scores of the nine scales agree more or less satisfactorily with clinical conclusions concerning the kind and degree of mental symptoms in about two out of three individual cases. In about one out of five cases the MMPI significantly exaggerates the psychopathology of an individual, if information from other sources serves as a criterion for judgment. Admissions of difficulties are not necessarily more valid than assertions of well-being.

Validity of the test. The assumption of the MMPI is that the accuracy of the subject's self-ratings is not a condition of the test's validity. The authors believe that the value of the test rests on what the patient says, not on the truth value of what he says. For example, it is clinically true that hysterics exaggerate their troubles to gain sympathy, but rating the MMPI statement "I think a great many people exaggerate their troubles in order to gain the sympathy and help of others" as true is scored as evidence of health, since most subjects who are not mental patients do not deny it. By contrast, when the statement about exaggeration of troubles is rated as false, points are added

to the hysterical scale because most hysterics rate it that way, denying the statement. What the patient does and what he thinks he does do not always coincide.

Statements are made in the first person singular in the belief that this encourages self-identification and self-references. However, this use of the first person instead of the third person is incompatible with the anxiety-alleviating principle.

Auxiliary scales have been introduced in order to permit identification of unreliable MMPI test records. One of them is the lie scale. It consists of items that, when answered candidly, imply a socially undesirable attitude. "Do you ever tell a lie?" is a lie scale item. The vast majority of people do tell some lies. Denying this by answering the question with "no" results in adding some points to the overly virtuous individual's lie scale. Another question of this type inquires whether the subject's table manners are as good when he eats in the privacy of his house as when he eats with others. If someone gives incredible responses to too many such questions, his MMPI is suspect. He is too good to be true; he tries too hard to make a good impression.

Another auxiliary scale consists of the number of "no" responses. A large number of denials tends to invalidate the test; it reveals an attitude of extreme guardedness. On the other hand, too small a number of "no" answers may indicate too great a suggestibility or lack of judgment, which also renders the test undependable.

The third scale, the K scale, was designed to discriminate between faking good at one pole and faking bad at the other pole of the bipolar scale. The chief aim of the K scale is to clarify the meaning of a borderline scale result by ascertaining whether the subject tended to exaggerate his strength or his weakness.

Many mental patients manage to produce normal MMPI profiles; that is, the peaks of all scales are within the middle range of T scores, between 30 and 70. But only 10 to 15 per cent of mental patients can *deliberately* simulate a normal profile. Those who fail in this attempt succeed only in making their MMPI look more abnormal. This shows that the lack of frankness and the pseudonormality can be a function of unconscious defenses against anxiety as well as a deliberate effort of self-concealment. The test gives better results when the subject feels it is to his advantage to be frank and to admit weaknesses; it is usually unreliable when he feels it is not to his advantage to be trustful and guileless.

As the subject's understanding of the content and intent of the MMPI questions increases, his capacity to modify his spontaneous answers to the questions in anticipation of the conclusions the examiner will draw from them also increases. This is true even of psychotics. Mild and intellectually average or superior schizophrenics evaluate themselves, as a rule, more normal than the normals. One difficulty of the test is that the number of deviant responses is relatively small, and, as a rule, subjects appear more stable in the MMPI than they actually are.

It may be that the MMPI has reached its highest level of perfection and cannot be improved upon. The paper and pencil personality inventories have definite

limitations even when they are as sophisticated in structure as the MMPI.

Interpretation. The majority of all mental patients produce MMPI profiles in which the D (depression) and Pt (psychasthenia) scales have the highest peaks and the T scores exceed 70 on both of them. This is to be expected, since anxiety and depression are the most frequent mental symptoms and since the existence of both tends to be associated with obsessive-compulsive tendencies; without the latter, symptoms would not persist. Phobias, forms of obsessiveness, are suggested by the Pt being the highest peak scale, provided it scores above 70. Profiles with Pt and Hy (hysteria) as the highest peaks point to psychoneurosis.

When both Pa (paranoia) and Sc (schizophrenia) score highest and when the T scores are above 70, the probability of schizophrenia is high. However, when only Sc scores above 70, the diagnosis is not certain. This is not surprising, since early or mild schizophrenics have all kinds of symptoms; schizoid withdrawal and reserve need not be their outstanding feature. There are schizophrenics with well developed hysterias, depressions, or marked anxiety states. This explains, in part, why the MMPI is a poor diagnostic aid but a better tool for the detection and measurement of psychopathological reaction patterns.

Although relatively little is known about the Ma (mania) scale, studies have shown that there is some positive correlation between Ma scores on the one hand and sociability and activity on the other. T scores of over 70 on both Sc and Ma may signify catatonia. High scores on both Ma and Pd (psychopathic deviation) are associated with delinquent behavior, impulsiveness, immaturity, rebelliousness, hostile aggressiveness, and low frustration tolerance.

Patients with high scores on the three scales of D, Hy, and Hs (hypochondriasis) are conspicuously ill with various psychosomatic symptoms. They are inclined to be resigned and passive. They lack assertiveness. They are irritable but dependent, tense, timid, and worrisome. When there is a high score on Pt as well as on D, Hy, and Hs, the patient is likely to be a severe alcoholic, especially a male subject. Such patients are very demanding and very frustrated in the pursuit of gratification of their demands.

Pt is the anxiety and tension scale that modifies the other scales because it is associated with alertness to potential, overwhelming, and unknown danger. Though disturbing, anxiety intensifies interest in reality. Patients with high scores on Sc and Pa alone are, on the whole, sicker than those who, in addition to these two, have a high score also on the Pt scale. Many patients with high Pt and D scores have good work records on routine jobs that do not call for initiative, self-expression, courage, or sense of responsibility for others. When the scores on Pt, D, and Mf (masculinity-femininity) are all high, the individual

is likely to be inhibited, nondelinquent, effeminate, and neurotic.

Patients with high scores on Pa and Pd are very different. They tend to be moody, assaultive, and heavily alcoholic. They make more frequent suicidal attempts as a group than patients with other MMPI profiles. The MMPI discriminates rather well between depressed and nondepressed psychotics, which is important in the case of potential suicides.

Factor analysis of personality. Although the statistical procedure known as factor analysis can be applied to any matrix of correlational coefficients, by far the greatest majority of factor analytic studies in psychology are done with personality questionnaires. Raymond Cattell has made the most extensive, systematic use of factor analysis and produced the 16 Personality Factors questionnaire in 1950.

Factor analysis has as its aim the discovery of the minimal number of statistical factors with the lowest possible correlations among them that would account for the obtained correlational coefficients. Factors, then, are a mathematical summary, the content of which depends on the summarized data. When the correlated tests, the subjects, or the complexity of the tests varies, the factors change. Some of the correlations are not high enough to trust the system of the questionnaire factors.

Drawbacks. A questionable assumption of psychological factor analysis is that positive correlations between test variables are due to a common source trait (factor) in the subjects' personalities. Another assumption is that traits correlated in one individual are correlated also in other persons. Because of the diversity of personality structures, this is frequently not the case, thus destroying the universality of factors. If they are not universal, the prerequisites of their applicability must be determined. The acquisition of such knowledge would be a formidable task. Lack of universality greatly decreases the usefulness of the factors and dampens the desire to go through the lengthy procedures of factor analysis.

The allure of factor analysis is the promise of objectivity and precision. This promise is spurious. For, once the factors are mathematically derived, they must be assigned a meaning; otherwise, they would remain meaningless. The meaning given is at best the result of a calculated guess regarding the common significance of the test items that mathematically constitute the factor. Without wild guessing, one cannot extract from factor analysis more than one puts into it; Cattell's factors suffer from all the weaknesses of personality questionnaires. In the process of assigning meaning to factors, the gate is opened to unreliable subjectivity, which the laborious and copious statistical calculations were designed to remove. Examples of the two-dimensional factors are "enthusiasm versus melancholia," "cyclothymia versus schizothymia," and "will control versus character stability."

The same arguments apply a fortiori to other factor analytic studies based on personality questionnaires, whether they pertain to inner mental attitudes, overt conduct, neuropsychiatric diagnoses, prognosis, or other aspects of normal and abnormal personality.

Suggested Cross References

For information regarding other psychologic tests see Benton's section (Section 12.2) on psychological tests for organic brain damage in this chapter as well as Anastasi's section (Section 39.3) on psychological tests for children in Area H, on child psychiatry. The clinical syndromes mentioned in this section, such as

schizophrenia, homosexuality, and depression, are covered in detail in Area F, on the psychiatric disorders. Concepts of perception and cognition which are fundamental to the projective and intelligence tests described in this section are discussed in Sections 3.1 and 3.2, respectively, in Area B, on the basic behavioral sciences. Test findings characteristic of specific psychiatric disorders such as schizophrenia, depression, mental retardation, and organic brain disorders are covered in Area F. A summary of information on psychological tests used in psychiatry is presented in the chart by Fensterheim in this chapter.

12.2 PSYCHOLOGICAL TESTS FOR BRAIN DAMAGE

ARTHUR L. BENTON, PH.D.

As the primary integrative mechanism of the total human organism, the central nervous system (CNS) mediates mental processes, complex behavioral reac-

tions, and somatic and vegetative responses. Consequently, disease or injury at the higher levels of the CNS is likely to be reflected in disturbances in mentation, feeling, and conduct. It is this fundamental fact that makes behavioral assessment a necessary part of clinical neurological evaluation, particularly when the question of disease involving the cerebral hemispheres has been raised. Such behavioral assessment can be accomplished in various ways: by direct observation of the patient's behavior in a natural setting, from the description by informants of aspects of the patient's present and past conduct, by questioning and observation during the interview, and by tests. All these approaches have proved to be useful in aiding diagnostic inference.

The method of tests differs from the other approaches in a number of respects. A test is essentially an attempt to elicit a specific type of behavior under relatively controlled stimulus conditions. This control is achieved by presenting a defined task or stimulus complex (for example, arithmetic problems, material for memorization, inkblots) in a defined manner to every patient. Moreover, the task or stimulus complex is of such a nature as to evoke behavior that is relatively easy to describe in objective or quantitative terms. Because of their relatively objective and quantitative nature, psychological tests are often conceived of as laboratory procedures, comparable to serology, electroencephalography, and radiology procedures, with respect to their role in neuropsychiatric diagnosis. This perspective emphasizes the distinctive contribution these methods can make, as contrasted with the more global forms of behavioral evaluation; that is, they provide findings characterized by a degree of precision and objectivity that cannot be obtained through the use of the other methods.

Furthermore, psychological tests, when considered as laboratory procedures, are seen in their proper role as aids to or components of the total clinicodiagnostic process. Nevertheless, it is important for the clinician to appreciate the fundamental difference between serology or electroencephalography procedures and neuropsychological tests. The former deal with infrabehavioral events, the latter with behavioral events. Classes of phenomena not otherwise open to analysis are disclosed through the use of the infrabehavioral methods. In contrast, neuropsychological tests deal with overt behavior, a class of phenomena already available, actually or potentially, for global clinical evaluation. It should be noted that the majority of psychological tests represent attempts to objectify and quantify impressions already gained from general clinical observation.

Thus, to a considerable degree, the aspects of behavior sampled by clinical observation and by neuropsychological tests are the same (for example, speed of response, level of comprehension, use of language), but the tests assess these aspects of behavior with greater reliability and precision. The tests go on to

sample other aspects of behavior, such as visual memory and psychomotor skill, that are not readily elicitable in the general examination. Hence, the employment of neuropsychological tests serves both to validate the impressionistic findings of the general clinical examination and to provide additional information about other aspects of intellect and personality.

It is a truism that behavior has multiple determinants and that the same behavioral deviation may be produced by factors of a diverse nature. Hence, when behavioral deficits that raise the question of cerebral dysfunction are observed in a patient, it is necessary to consider other possible determinants of defective performance before the inference of cerebral disease is made. Among these are: (1) lack of adequate cooperation and effort on the part of hostile, asocial, or paranoid patients; (2) lack of mental energy in patients who are depressed or seriously depleted by systemic extracerebral disease; (3) inattention and concentration difficulty associated with preoccupation or intense anxiety; (4) simulation or exaggeration of mental incompetence, particularly when questions of compensation for injuries received or a pension are involved; and (5) poor comprehension and task adjustment on the part of culturally handicapped patients.

Survey of Neuropsychological Tests

General intelligence. The clinical observation that patients with cerebral disease may show an over-all behavioral inefficiency and be unable to meet the diverse intellectual demands associated with the responsibilities of daily life dates back many centuries. The observation is expressed in the global concepts of dementia and deterioration. The normal counterpart of these pathological concepts is the concept of general intelligence, which is equally global in nature. The application of this concept in clinical practice assumes that there is a sufficient degree of positive correlation among various intellectual abilities to warrant the conclusion that a single general ability is a significant component in performance on diverse intellectual tasks—verbal skills, mathematical abilities, abstract reasoning, and the like. Granted this assumption, it is justifiable to derive a single score from a battery of mental tests and to use this score as an index of general intelligence. This is what is done when an intelligence test battery such as the Wechsler Adult Intelligence Scale (WAIS), which consists of 10 subtests, is administered and the patient's scores on the various subtests are combined into a total score, which yields an I.Q. (See Table I.)

Obtained I.Q. versus expected I.Q. In the United States, the WAIS is by far the most widely used test battery for assessing general intelligence in adult subjects. In its clinical application, a number of procedures have been used to evaluate the possibility of a decline in general intelligence that may be ascribed to the presence of cerebral disease. The most direct ap-

TABLE I

Tests for Assessing Brain Damage

Category	Sub Categories	Remarks
General scales	Wechsler Adult Intelligence Scale (WAIS) Stanford-Binet Wechsler Intelligence Scale for Children (WISC)	Given the availability of adequate normative standards in relation to the patient's educational and cultural background, a performance significantly below expectations should raise the question of cerebral damage. This generalization applies to both adults and children.
Reasoning and problem solving	Abstractions (Shipley) Progressive matrices (Raven) Proverbs (Gorham) Perceptual mazes (Elithorn) Object and color-sorting tests (Goldstein and Scheerer)	Performance level is closely related to educational background and premorbid intellectual level. In general, the clinical application of these tests is more useful in the case of educated patients. If specific language and perceptual defect can be ruled out as determinants of defective performance, failure suggests frontal lobe involvement or diffuse cerebral disease.
Memory and orientation	Immediate auditory memory—repetition of digits Immediate auditory memory—reversal of digits Immediate visual memory (Benton, Graham-Kendall) Recent auditory memory—words or stories Recent visual memory—words or pictures Temporal orientation (Benton, Van Allen and Fogel)	For complete assessment, a number of memory tasks (auditory versus visual, verbal versus non-verbal, immediate versus recent) should be given. Minor defects in temporal orientation may be elicited and suggest weakness in recent memory.
Visuoperceptive and visuoconstructive	Identification of hidden figures (Teuber-Weinstein-Rudel) Identification of fragmented figures (Street-testalt) Block design construction (Kohs, Goldstein-Scheerer, Wechsler) Stick arranging (Goldstein-Scheerer) Copying designs (L. Bender, Benton visual retention) Three-dimensional block construction (Benton-Fogel) Inkblot interpretation (Rorschach, Holtzman) Perceptual mazes (Elithorn) Responsiveness to double visual stimulation (M. B. Bender)	These types of task are relatively sensitive indicators of the presence of cerebral disease. Analysis of qualitative features of performance and comparison of performance level with the status of language and reasoning abilities often provide indications with regard to locus of the lesion.
Somatoperceptual	Tactile recognition (Parker, Ross) Finger recognition (Benton) Right-left orientation (Benton) Responsiveness to double tactile stimulation (M. B. Bender)	Frequently useful indicators of the presence and locus of cerebral disease.
Language	Token test (De Renzi-Vignolo) Abstractions (Shipley) Proverbs (Gorham) Word fluency (Benton-Spreen-Fogel) Illinois test of psycholinguistic abilities (Kirk-McCarthy)	Test performance is dependent on educational background, and it is essential that clinical interpretation allow for this and other possibly significant factors. In adult patients, defective performance (particularly in relation to other abilities) suggests dysfunction of the cerebral hemisphere that is dominant for language. In children, defective performance does not have this localizing significance but does raise the question of the presence of cerebral damage.
Attention, concentration, and motor abilities	Continuous performance test (Rosvold) Visual vigilance (McDonald-Burns) Reaction time (Blackburn-Benton-Joynt) Motor impersistence (Garfield) Imitations of actions (Bergès-Lézine)	Valuable behavioral indicators of the presence (and sometimes locus) of cerebral disease that deserve more extensive clinical application.

proach is to compare a patient's obtained age-corrected I.Q. score with the age-corrected I.Q. score that may be expected in view of his educational background, cultural level, and occupational history. A negative discrepancy, that is, obtained I.Q. below expected I.Q., beyond empirically established normal limits may be interpreted as indicating a possibility of the presence of cerebral disease. This procedure has been shown to have considerable clinical utility. However, it also has serious limitations since, as is well known, many patients with unquestionable cerebral disease do not show an over-all decline in general intelligence of sufficient severity to be reflected in a significant lowering of the WAIS I.Q. score. Consequently, this procedure may be expected to yield a fair proportion of false negative results.

A variant of this procedure is to compare obtained and expected I.Q. scores on the WAIS performance scale, which consists, for the most part, of nonverbal and relatively novel tasks. This has proved to be fully as useful as the comparison of full scale I.Q. scores.

Sensitive versus insensitive tasks. Since it has been found, at least in nonaphasic patients, that certain types of performance tend to be more seriously affected by cerebral damage than others, a second approach consists of comparing performance level on presumably less sensitive tasks with that on more sensitive tasks. Thus, verbal scale I.Q. is compared with performance scale I.Q., or performance on a set of insensitive tests (for example, information, picture completion) is compared with performance on a set of sensitive tests (for example, arithmetic, block designs). Although widely employed by clinical psychologists, these procedures, which rely on a discrepancy score or a deterioration ratio within the test battery itself, have been found to possess only relatively modest clinical utility.

Impaired performances. A third approach would be to focus attention on those subtest performances (block designs, arithmetic, digit symbol) that clinical experience indicates are most frequently and severely impaired in patients with cerebral disease. This is a rational procedure, but full exploitation of its clinical value depends on the availability of valid and precise normative standards of performance in relation to age, educational background, and sex. In a given clinical setting, the establishment of such standards may require the development of local norms, since test performance patterns may vary in different parts of the country and among different cultural groups.

Reasoning and problem solving. Impairment in the capacity for abstract reasoning and reduction in behavioral flexibility when confronted with an unfamiliar situation are well known behavioral characteristics of the brain-damaged patient. Both types of deficit are important components of Kurt Goldstein's concept that the fundamental behavioral change resulting from cerebral disease is "impairment of the abstract attitude."

A relatively large number of special tests designed to measure each of these capacities have been devised. Among those that have shown clinical usefulness are the Shipley abstractions, Raven's progressive matrices, the Gorham proverbs test, the Porteus mazes, the Elithorn perceptual mazes, and the Goldstein-Scheerer sorting tests.

Defective performance by brain-damaged patients on such tests is frequent enough, but it is important to determine the *basis* for a given patient's failure. Language skills play a role in performance on some tests, and other tests make demands on visuo-perceptive capacity. Hence, it is essential to rule out language and perceptual handicaps as determinants of a defective performance before making the inference that it indicates impaired reasoning or problem-solving ability.

The tests mentioned have proved to be particularly valuable for disclosing behavioral deficit in the neurologically negative patient with frontal lobe or beginning diffuse cerebral disease who shows no specific sensory, perceptual, language, or motor impairments and who, on initial encounter, may appear to have a functional psychiatric disorder. Conversely, these tests are practically useless for the specific purpose of inferring brain disease when applied to unintelligent or uneducated subjects or to individuals suffering from psychosis.

Memory and orientation. Impairment in certain types of memory, most notably short term and recent memory, is a prominent behavioral deficit in brain-damaged patients and is often the first sign of beginning cerebral disease and of old age. For this reason, procedures for the assessment of memory functions have always found a prominent place in the mental status examination and in psychological test batteries.

Memory. This catch-all term covers the retention of all types of material over different periods of time, involving diverse forms of response. Empirical studies have shown that a subject's performance may vary significantly as a function of a number of factors, such as the sensory modality involved (auditory versus visual), the type of material to be remembered (verbal versus nonverbal), or the form of response required (recognition versus reproduction). For this reason, the neuropsychological examiner is more inclined to give specific memory tests and to evaluate them separately than to utilize an omnibus battery, such as the Wechsler Memory Scale, which provides for a brief assessment of a large variety of performances and which yields a single score in the form of a memory quotient. However, this type of instrument has some usefulness as a screening device, despite the fact that it does not adequately measure such memory functions as visual retention and also despite the fact that combining the separate scores into a single total score is a dubious procedure.

Immediate memory. A differentiation between im-

mediate memory, recent memory, and remote memory is often made, and this distinction proves meaningful from a clinical standpoint. For example, it is a common observation that patients with a Korsakoff syndrome, showing a pervasive and severe impairment in recent memory, may be able to perform well within normal limits on tasks involving the immediate repetition of digits or sentences and may show preserved memory for events in the remote past.

Immediate memory may be defined as the reproduction, recognition, or recall of perceived material within a period of not more than 10 seconds after presentation. It is most often assessed by digit repetition and reversal (auditory) tests and memory for designs (visual) tests. Both have been found to discriminate significantly between brain-damaged and control subjects, but the visual task is the more sensitive indicator.

The precise reason for this difference in discriminating power is not known. The relatively novel nature of the task of drawing designs from memory may be an important factor here, or perhaps the difference in sensory modality is the crucial factor. A comparative study of the discriminative efficiency of auditory and visual digit span tasks would be of interest in this regard and might provide information of clinical utility.

In any case, both an auditory-verbal task such as digit span (or memory for words or sentences) and a nonverbal visual task such as memory for designs (or faces) should be given to assess a patient's immediate memory. Despite the fact that group studies show a significant positive correlation between performances on the two types of tasks, dissociation (that is, adequate performance on the one and defective performance on the other) is not rare and may be of clinical interest. Patients with lesions of the right hemisphere are likely to show significant defect on visual nonverbal tasks while performing on a normal level on auditory verbal tasks. Conversely, patients with left hemisphere disease, including those who are not aphasic, are likely to show deficit on the auditory verbal tests with variable performance on the visual nonverbal tasks.

Recent memory. This refers to the reproduction, recognition, or recall of perceived material after a given period of time (10 seconds or longer) has elapsed following the initial presentation. It is typically assessed by measuring the patient's memory for a story read to him, for items in a display of words or pictures or abstract forms, or for such learned material as lists of words or pictures. This type of task provides one of the more sensitive indicators of the presence of cerebral disease. However, since quality of performance is closely dependent on level of effort and attention, the examiner must carefully consider other possible determinants before interpreting failure on these tasks as a sign of brain damage.

Memory for remote events and orientation for per-

son or place. These are rarely disturbed in the brain-damaged patient who is not psychotic or severely demented.

Temporal orientation. Minor defects in temporal orientation are not at all rare. These are often overlooked by the clinical examiner because of his tendency to regard slight inaccuracy in giving the day of the week or of the month as being inconsequential. But, in point of fact, objective assessment based on empirically derived normative standards has shown that 20 to 25 per cent of nonpsychotic patients with cerebral disease are likely to show significant inferiority with respect to precision of temporal orientation.

Perceptual and perceptuomotor performances. Many brain-damaged patients, when examined by means of appropriate techniques, show defective analysis of complex perceptual situations and/or inability to translate their perceptions into appropriate motor action. Unless the impairment is of a gross nature (as in visual-object agnosia or dressing dyspraxia) or interferes with a specific occupational skill (such as typesetting or assembling a machine), these deficits are not likely to be the subject of spontaneous complaints. Nevertheless, objective testing discloses a remarkably high incidence of impaired performance on visuoanalytic, visuospatial, and visuoconstructive tasks in brain-damaged patients, particularly in those with disease involving the right hemisphere. The impairment also extends to tactile and auditory perceptual task performances.

Many tests have been devised to measure these capacities; only a few of them can be mentioned here. Higher level visuoperceptive capacity may be assessed by means of tests involving the recognition of hidden figures and fragmented figures. Visuoconstructive capacity may be assessed by tests calling for block design construction, stick arranging, copying designs (for example, Bender-Gestalt, see Figure 1), and three-dimensional block model construction. Defective capacity for visual analysis and synthesis is also brought out in performance on the Rorschach test by poor percepts (*F*-), failure to see movement (low *M*), and paucity of response (low *R*).

Performance on the Elithorn perceptual mazes often discloses the same type of impairment. Patients with apparently intact stereognostic capacity, as evidenced by their accurate recognition of palpated objects in the neurological examination, often show defects in tactile recognition when subjected to more demanding test procedures. Defects in auditory discrimination and recognition may also be manifested. Somatoperceptual defects, such as impairment in finger localization or in the identification of the right and left side of one's body, are sometimes revealed by appropriate testing. Elementary perceptual integration within the visual and tactile modalities can be assessed by application of the method of double simultaneous sensory stimulation.

The application of these perceptual and perceptuo-motor tests in the detection of the presence of cerebral disease has proved quite rewarding and possesses certain advantages. Although not culture-free (no behavioral performances are), these tests are generally less dependent on educational level and cultural background than many of the more intellectual tasks. Many of the tests are relatively sensitive indicators of the presence of cerebral disease. Finally, they often provide suggestions with regard to the probable *locus* of the cerebral lesion and thus may help to offer a focus for further neurological exploration.

Language functions. Gross impairment in language functions in the form of frank aphasia can scarcely be overlooked by the psychiatrist, although the less experienced examiner may sometimes misinterpret some types of defect as signs of dementia or psychosis. On the other hand, it is quite likely that less severe disturbances of language expression and comprehension may go unrecognized for the simple reason that the interview or the application of a few simple tests for aphasia fails to bring them out.

Relatively minor defects in the use of the instrument of language may be valid indicators of the presence of disease of the dominant hemisphere. These defects are often the first signs of a developing aphasic disorder. Higher level language tests have been successfully used to indicate the presence of such a sub-clinical or latent aphasia. A number of instruments can be used for this purpose. The token test of De-Renzi and Vignolo brings subtle as well as gross disturbances in the comprehension of oral language into sharp relief. The Shipley abstractions make demands on verbal reasoning that the patient with latent aphasia is unable to meet; understanding of the meaning of proverbs is likely to be poor. Verbal-ideational impoverishment is shown by defective performance on word fluency tests.

Performance on all these tests is heavily dependent on educational background, and clinical interpretation must allow for this variable, and for other possibly significant factors, such as age and sex. When these corrections are made, these tests provide valuable information that can aid in diagnosis. The sensitivity of performance level to the presence of disease of the dominant hemisphere negates the assumption that verbal abilities remain intact in nonaphasic patients with brain damage while nonverbal skills decline. The seeming disparity is a question of what tests are used to assess verbal abilities.

Speed and flexibility of response. It is a common clinical observation that some brain-damaged patients are quite slow in responding to diverse stimuli and have notable difficulty in modifying their behavior to meet the changing demands of a shifting situation. Objective quantitative methods of assessment not only confirm these observations in such patients but also disclose the same response retardation and behavioral rigidity in many others who may appear,

FIGURE 1. Test figures from the Bender Visual Motor Gestalt Test, adapted from Wertheimer. (From Bender, L. *A Visual Motor Gestalt Test and Its Clinical Use*. Research Monograph no. 3. American Orthopsychiatric Association, New York, 1938.)

on clinical ground, to be unremarkable in these respects.

Reaction time studies have shown that both simple and choice visual reactions are significantly retarded in 40 to 45 per cent of nonpsychotic, brain-damaged patients. Moreover, patients with unilateral cerebral disease show clear retardation, even when the ipsilateral hand (on the unaffected side of the body) is used to effect the response. These results indicate that reaction time is a fairly sensitive indicator of over-all cerebral integrity and that retardation in reaction time reflects the presence of a cerebral lesion *regardless* of its locus. It may be noted that comparison of the reaction times of the right and left hands often provides an indication of the probable hemispheric locus of a focal lesion. This method deserves more extensive application as a diagnostic procedure, particularly when the question of differentiation between neurosis and cerebral disease is involved.

A variant of the simple reaction time experiment, in which the patient must react to successive presentations of different stimuli instead of to successive presentations of the same stimulus, provides an opportunity to measure behavioral flexibility on a basic sensori-

motor level. Excessive slowness in response to a stimulus that has been preceded by a stimulus in another sense modality (cross-modal retardation effect) is exhibited by both schizophrenic and nonpsychotic brain-damaged patients. Neurotic patients do not show this marked susceptibility to the cross-modal retardation effect.

Other measures of behavioral flexibility are provided by tasks in which the patient must modify his approach to a problem in accordance with changing requirements—color-form sorting, object sorting, and concept formation tests. The last type of test has been found to be particularly valuable in identifying patients with frontal lobe disease.

Attention and concentration. The capacity to sustain a maximal level of attention over a period of time is sometimes impaired in brain-damaged patients and is reflected by oscillation in performance level on a continuous or repeated activity. There is some evidence that this instability in performance is related to electroencephalographic abnormality and that the occurrence of inexplicable declines in performance is related temporally to the appearance of certain types of abnormal electrical activity. For example, Prechtl and associates were able to show that episodes of response retardation in a continuous performance task in epileptic patients coincided with the occurrence of diffuse flattening of the EEG.

A variety of tests have been devised to assess vigilance and capacity for sustained attention. Simple reaction time provides a convenient measure of variability and speed of simple responses and is possibly as discriminative and informative as assessments of performance on more complex and lengthy tasks. While the patient's median reaction time can be utilized as an index of speed, the standard deviation of his reaction times provides an index of variability that can be conceptualized as reflecting limitations in capacity for sustaining maximal attention. Intraindividual variability in both simple and choice reaction time has been shown to be significantly higher in brain-damaged patients than in matched controls. Among the more recent tests that have been developed for measuring attention and concentration is the continuous performance test of Rosvold et al., which has been shown to discriminate reasonably well between brain-damaged patients (both adults and children) and controls. Another test is a vigilance task, involving the detection of visual signals, developed by McDonald and Burns; it also discriminates significantly between brain-damaged patients and controls.

The clinical utility of these tests of attention and vigilance has not been adequately determined, and whether they deserve a place in the armamentarium of the clinical examiner is still an open question. Study along these lines will have to take into account the possible effects of drugs and of deviations in mood. Tests in this area seem to warrant further exploration, particularly since they furnish a type of task that in-

cludes the possibility of establishing a temporal correlation between performance and specified neural events.

Behavioral Indices of Brain Damage in Children

For various reasons, it is very popular today to make the diagnostic inference of brain damage to explain entirely or in part the deviant behavior of many children. In the majority of cases, the inference is made on the basis of behavioral observation (for example, hyperactivity, distractibility, motor awkwardness, destructiveness) and is *not* substantiated by infrabehavioral clinical or laboratory findings. The clinical psychologist is then called on to validate the diagnostic impression by means of tests. Since, to a considerable degree, his tests assess the same behavior as that on which the clinical diagnosis was based, the chances of confirming the diagnosis are rather high. The circular nature of this process and the fact that at no point has an independent, infrabehavioral criterion of brain damage played a role are obvious.

The clinical impression of brain damage most often rests on observation of the symptom complex of overactivity, restlessness, impulsivity, irritability, and unpredictability. Although the reality of this symptom complex with its significant relation to the presence of brain damage is undeniable, this is by no means *the* characteristic behavioral picture of brain damage in children. The behavioral consequences, if any, of early brain damage may take many forms, of which the hyperkinetic impulse disorder is only one. In fact, the latter is not a particularly frequent behavioral picture among children with unquestionable cerebral disease (tumor, trauma, degenerative disease). Furthermore, one must be prepared for the possibility, clearly indicated by animal studies, that early brain damage may result in very little or no behavioral deficit and that, when such deficit does appear, it is always less severe than that caused by a comparable cerebral lesion in adults. Thus, there is reason to believe that there are many brain-damaged children who are not identified by current methods of behavioral assessment.

These preliminary remarks are not intended to foster an attitude of nihilistic skepticism. They are made because they bear directly on the judicious use of test results by the psychiatrist when the question of brain damage in a child has been raised. The clinical psychologist may report (indeed, is likely to report) signs of brain damage in various test performances. Or he may report a normal profile of test performances. Whichever the case may be, it is important for the referring physician to be aware of the complexities of the situation so that he is in a position to place the test results in proper perspective.

In the following survey, emphasis is focused on the use of tests to infer brain damage in the nondefective child (that is, a child with an I.Q. of 80 or higher) of school age.

General intelligence. As in adults, general intelligence in children is measured by over-all performance level on an omnibus test battery. The most frequently used batteries are the Wechsler Intelligence Scale for Children (WISC) and the revised Stanford-Binet. A low level of general intelligence is probably the most constant behavioral result of brain damage in children. The failure in intellectual development may, or may not, be severe enough to place the child in the category of mental retardation. When the child is not retarded, his intelligence level still tends to be below expectations, based on the intelligence levels of his parents and siblings and taking into account his socioeconomic status. The identified nondefective, brain-damaged child from an average family is likely to have an I.Q. in the 80's, instead of the expected 100 to 110. The identified nondefective brain-damaged child from a superior family may have a higher I.Q., perhaps even as high as 120, but an appreciable difference in level between him and his siblings is usually found.

In contrast to the findings in nonaphasic adults with cerebral disease, the performance scale of the WISC does not seem to be more sensitive than the verbal scale to the effects of brain damage. This is understandable when one considers that in the adult such tests as information, vocabulary, and comprehension measure knowledge and skills acquired in the remote past, whereas in the child they are indices of the rate of acquisition of these skills.

As with all tests, the procedure of comparing observed with expected I.Q. in the nondefective child suspected of suffering from brain damage no doubt produces its share of false negatives, and special test methods should be utilized. With respect to the problem of possible false positives, if the clinician is not willing to accept a significant discrepancy between observed and expected I.Q. as evidence of brain damage, he should be prepared to explain the discrepancy on other grounds. This simple, straightforward approach to the behavioral diagnosis of brain damage in children deserves more widespread clinical application than is now accorded it.

Perceptual and perceptuomotor performances. These tasks constitute the favored procedure among clinical psychologists for disclosing behavioral deficit related to brain damage. Their application is based on the long standing observation that many brain-damaged children with adequate verbal skills show strikingly defective visuoperceptive and visuomotor performances.

The test most frequently employed is copying of designs, either from a model or from memory. Typically, about 25 per cent of brain-damaged school children of adequate verbal intelligence are found to perform defectively, that is, on a level exceeded by 95 per cent of normal children of comparable verbal intelligence. The task discriminates between brain-damaged children and those suffering from presum-

ably psychogenic emotional disturbance. Another type of perceptuomotor task that has been investigated is path tracing, as in the trail-making test.

Tasks involving the recognition of hidden figures, that is, figures imbedded in masking background, and the detection of patterns have also been utilized to probe visuoperceptive capacity and have disclosed inferior performance in brain-damaged children as compared with normal controls. Capacity for elementary perceptual integration within and across sensory modalities can be evaluated by double simultaneous stimulation and intersensory matching techniques; their application has yielded results of clinical interest.

Defective finger recognition and right-left orientation, often conceptualized as reflecting a disturbance in the body schema, are shown by some nondefective children with brain damage. Tests for these capacities deserve a place in any detailed examination directed toward the question of brain damage in a child of school age.

Language functions. Diagnostic evaluation of the child suspected of having brain damage has typically depended largely on assessment of his perceptual and perceptuomotor performances, but there is reason to believe that the status of his language abilities may be an equally sensitive indicator. It is not uncommon to find very poor development of language functions as compared with nonverbal skills in high grade mental retardates, and there remains the question as to whether this particular pattern of performance may not be the reason why many of these children are labeled retarded rather than brain-damaged. There is considerable evidence that aphasic children, those who show a gross maldevelopment of oral language abilities as compared with general mental level, suffer from brain damage. Moreover, a number of studies have raised the question of whether prenatal brain injury may not be a causative factor in at least some cases of developmental dyslexia. The finding of an excessively high incidence of electroencephalographic abnormality in dyslexic children points to the same conclusion.

All these considerations suggest that a careful analysis of language skills should be a part of the psychodiagnostic work-up in children suspected of having brain damage. The Illinois test for psycholinguistic abilities is an appropriate instrument for this purpose. Unless explainable in terms of cultural handicap, sensory deficit, or personality disturbance, observed deficit in this area should raise the question of brain damage.

Attention and concentration. It is commonly reported by parents and teachers that a brain-damaged child will show inexplicable inconsistency in behavior, now performing at one level, then at another. This everyday observation has been amply confirmed by analyses of performance on a variety of tests that require, either deliberately or incidentally, sustained

attention and concentration. For diagnostic purposes, the Continuous Performance Test can be utilized with older school children as well as adults to probe this capacity. Variability in simple reaction time provides a rational measure in younger children that can be applied clinically if appropriate normative standards are available as a basis for evaluating performance.

Motor performances. Motor awkwardness and inability to carry out movement sequences on command or by imitation are not uncommonly seen in brain-damaged children. Some of them show a virtual ideomotor apraxia and/or dressing dyspraxia. A variety of tests are available for the assessment of manual dexterity, for example, manipulations with tweezers, paper cutting, and peg placing. The new imitation of actions tests of Bergès and Lézine promise to be useful for the evaluation of higher level praxis and would have even greater utility if an American standardization and revision were undertaken.

Motor impersistence—inability to sustain an action initiated on command, such as keeping the eyes closed or maintaining central fixation during confrontation testing of visual fields—is seen in a small proportion of adult patients with cerebral disease. However, it is shown with remarkably high frequency by nondefective, brain-damaged children. Many mental defectives also show excessive motor impersistence. Clinical studies of this rather singular disability suggest that it may well prove to be an extremely valuable symptom of brain damage in the younger school age child.

Suggested Cross References

Several sections in Area B, on basic behavioral science, deal with concepts that underlie the use of psychological tests in the assessment of organic brain damage. Basic concepts of intelligence and language are discussed in Martin Deutsch's section (Section 3.2) and perception and memory are covered by Cynthia Deutsch (Section 3.1) and E. Roy John (Section 2.10), respectively. The clinical disorders to which the tests are applicable are discussed in detail in Area D, on neurology; in Area F, on the psychiatric disorders; and in Area H, on child psychiatry. Of special relevance are the sections on organic brain syndromes in children by Laufer (Section 42.3) and on dyslexia and other disorders of language functions by de Hirsch (Section 40.4). For a discussion of the assessment of brain damage by means of the psychiatric examination, see Section 11.2 by Sands in the previous chapter. Solomon discusses the neurological examination (Section 10.1) in the chapter on neurology.

HERBERT FENSTERHEIM, Ph.D.¹

This table is intended to provide a quick survey of some commonly used clinical psychology instruments. They are grouped into measuring devices, which provide scores and normative standards; behavior samples, which allow qualitative observa-

tions within given areas of psychological functioning; and projective techniques. More detailed information concerning these instruments may be found in the *Mental Measurements Yearbooks*.

Instrument	Description	Comments
MEASURING DEVICES		
Benton Visual Retention Test	An individually administered test designed to measure visual memory, used for subjects 8 years of age and older.	This is one of a class of instruments used to investigate memory functions. It is most useful in differential diagnosis and in the evaluation of brain damage.
Cattell Infant Intelligence Scale	A downward extension of the Stanford-Binet test to cover ages 3 to 30 months.	This test has little predictive value for future intellectual level, particularly in the early ages. However, it does yield a good description of current functioning and is useful for the early diagnosis of mental retardation and brain damage.
Gesell Developmental Schedule	A scale based on behavioral observations, to measure development in different areas from the age of 4 weeks to 6 years.	Although the scale yields poor predictions for later developmental quotients, particularly during the early ages, it does yield a satisfactory picture of current functions. Clinically, it is most useful as a supplement to other data or when successive measurements are taken over a period of time.
Minnesota Multiphasic Personality Inventory	A questionnaire-type of personality test for ages 16 years and over. May be administered individually or in groups. Yields 14 scores in scales representing diagnostic categories (such as hysteria, schizophrenia) and test-taking behavior (such as lying).	Besides the scales noted in the test manual, other scales, such as ego strength, have been reported in the literature. Although the administration and scoring of this test are quite simple, the interpretation of the score profiles may become rather complex and requires considerable experience.
Stanford-Binet Intelligence Scale, Form L-M, 1960	An individually administered age scale intelligence test designed to range from 2 years up. This is a revision based on the 1937 Forms L and M. It yields a mental age and a deviation I.Q.	This scale presents a wide variety of items and item difficulty. It is organized by item difficulty (i.e., age level). The choice between this scale and the WISC is often a matter of the preference of the individual clinician, with the Stanford-Binet usually being the most helpful at the lower age levels and at the extremes of intelligence.
Wechsler Adult Intelligence Scale (WAIS)	An individually administered intelligence test for ages 16 years and over. It yields scores for 11 subtests as well as verbal, performance, and full scale I.Q.s.	The items of this scale are organized according to the task presented, with a separate score for each type of task. Besides yielding information concerning the intellectual and cognitive functions, analysis of the pattern of subtest scores and qualitative examination of the protocol may yield information concerning the impact of psychopathology in these areas.
Wechsler Intelligence Scale for Children (WISC)	A downward extension of an earlier form of the WAIS to cover the ages below 16 years. Yields scores similar to the WAIS (one additional optional test) but with subtest scores based on chronological age; covers ages to 16 years.	As with the WAIS, the scale is often used for more than the determination of level of intelligence. The grouping of items by type of task involved makes it easier for the clinician in actual practice to use it as an instrument to investigate the impact of pathology in the intellectual and cognitive areas.
Vineland Social Maturity Scale	An individual interview schedule aimed at determining rate of development. An age scale, it covers from birth to maturity. It yields a development quotient (D.Q.), which is the ratio of developmental age to chronological age.	This scale is simpler to administer and to score than is the Gesell scale, but it is based on reports rather than on direct observation. It does furnish a helpful picture of current developmental status, and it is strongest when used to supplement other data or to provide successive measures over time.

¹ Assistant Professor of Psychiatry, New York Medical College; Psychologist, Metropolitan Hospital, New York, New York.

Instrument	Description	Comments
BEHAVIOR SAMPLES		
Bender-Gestalt Test	An elicitation of visual-motor behavior by having the patient copy a set of geometric designs. Various modifications of administration may be introduced, such as having the designs redrawn from memory.	Although several scoring systems have been developed for this test, it is usually used qualitatively. Deficits in this area are often associated with brain damage, and the test is most used for differential diagnosis of brain damage. It may also be used to investigate developmental and intellectual levels in children and the characteristics of ego functions in adults. A number of clinicians use the instrument as a projective technique.
Examining for aphasia (Eisenson)	A systematic survey of the ability to receive and to express meaning through different modalities. It includes the aphasias, agnosias, and apraxias.	This instrument provides for behavior samples in various areas of language and symbolic function and at several levels within each area. As a quick survey, it is extremely useful where brain damage is suspected. However, further examination is usually necessary for treatment planning.
Goldstein-Scheerer Tests of Abstract and Concrete Thinking	A battery of five tests (cube test, color sorting, object sorting, color form sorting, stick test) to examine the ability to attain and to maintain the abstract attitude.	These tests afford opportunities to observe the patient attempting to solve problems that require abstraction and shifts in abstractions. Although other thought disorders, such as schizophrenic thinking, may be elicited, concrete thinking tends to be highlighted. The tests are most used for the diagnosis and the evaluation of brain damage.
Concept Formation Test (Kasanin and Hanfman)	A complex problem of grouping the Vigotsky Blocks is presented. Clues given and explanations of groupings are questioned.	The attempts to solve the complex problem provides opportunity to observe the patient's modes of thinking. The test is particularly useful in revealing patterns of schizophrenic thinking.
PROJECTIVE TECHNIQUES		
Blacky Pictures	A series of 11 cartoons about a dog (Blacky) and his/her family. The patient makes up stories, answers more structured questions, and indicates like-dislike for the pictures.	The stimulus pictures depict different stages of psychosexual development. Its major use is with children, but it can be used with adults. Some writers suggest the following sequence: Blacky with younger children, CAT with older children and adolescents; TAT with adults. This, however, is very much at the discretion of the individual clinician.
Draw A Person	The basic instruction is simply to draw a person, then to draw a person of the opposite sex. Many elaborations exist, including interviews about figures drawn.	This is one of a number of drawing projective techniques, including the drawing of a house, tree, person; of the family; of animals. The figure drawings, in general, may be interpreted as yielding data concerning self-concept, perception of significant figures, problem and conflict areas, mood, affect, and anxiety.
Rorschach	A series of 10 symmetrical inkblots. The patient tells what he sees in each. This is followed by an inquiry concerning the responses. Different sets of stimulus cards are available, but the original Rorschach plates are by far the most frequently used.	This is the most useful single instrument of the clinical psychologist. Through analysis of perception, cognition, and content, information concerning almost every aspect of psychological organization may be revealed.
Sentence Completion Test	Incomplete sentences are completed by patient (e.g., "My mother—"). Sentences may be aimed at specific potential conflict areas. Standard forms, such as the one by Rotter, are available.	This technique may be used at different levels from the prediction of overt behavior to the uncovering of deep personality dynamics. It yields data concerning conflict areas and emotional attitudes. This technique has the advantage of flexibility, for the skilled clinician may devise incomplete sentences tailored for a specific patient.
Thematic Apperception Test (TAT)	Patient makes up stories about stimulus pictures. Some pictures are specially designed for girls, boys, women, or men. Other sets of stimulus cards for special groups are available, such as the Children's Apperception Test (CAT), which uses pictures of animals.	This test helps to furnish the content of the patient's inner life. It may be said with some truth that the Rorschach furnishes the skeleton on which to hang the flesh and blood of the TAT. It yields data concerning, among other things, needs, pressures, self-concept, motives, fantasies, attitudes, and feelings.

12.3 SOCIAL SERVICE INFORMATION

C. KNIGHT ALDRICH, M.D.

A satisfactory psychiatric diagnosis usually requires more information than can be obtained from the direct psychiatric, psychological, or physical evaluation of the patient. It requires an evaluation, to the extent possible, of the total setting of the illness, including the environment and the people who are and have been significant in the patient's life. Family members are the usual sources of this kind of information. They can also provide an alternative, if not necessarily a more objective, view of the symptoms and the course of the illness, of the patient's personality and its development, and of the character of his interpersonal relationships and his adaptation. The social worker's contacts are not limited to relatives but may include other community resources when indicated, such as social agencies, clergy, and, usually in collaboration with the psychiatrist, the family physician or other medical resources.

Role of Social Worker

Although in most cases the psychiatrist can interview the relatives, the social worker's participation has distinct advantages. He offers the relatives a professional member of the psychiatric team who is primarily concerned with them and with whatever problems have developed in their lives as a result of the patient's illness; the psychiatrist, on the other hand, is primarily concerned with the patient and his problems. Furthermore, and particularly important with adolescent patients, the social worker's participation makes it unnecessary for the psychiatrist to communicate directly with the relatives; therefore, he does not appear to be relaying the patient's confidences back home. However, this advantage is lost if the psychiatrist uses the social worker as an intermediary for the transmission of information the patient has considered confidential, for the patient usually finds out what has transpired.

The social worker participates in the diagnostic assessment in most psychiatric training centers, and the psychiatric resident learns to rely on the social worker for several aspects of the work-up. He may be unprepared, therefore, for the situation that prevails in private practice. There, particularly in out-patient practice, he must usually do his own intake and secure his own social history. It is important, therefore, for the resident to learn about the technique as well as about the results of social work interviewing in his training years.

Participation of Social Worker

Goals. The social worker was originally concerned primarily with the mechanics of disposition—whether the discharged patient would have a place to live and enough to live on. To obtain this information usually required a knowledge of the family relationships, and, as the usefulness of this knowledge in diagnosis became apparent, the social worker began to interview relatives at the beginning of the patient's clinic or hospital experience.

Some of the information obtained from interviews with family members simply supplements information provided by the patient, and some—the history of a child's early development, for example—is inaccessible to the patient. If the family provides material the patient could have provided but has withheld because of fear or mistrust of the psychiatrist, it must be managed with considerable care. If the patient discovers that his relatives have revealed material he wishes to withhold, he will resent what he considers their betrayal, regardless of their benevolent motivation. If he discovers that the psychiatrist has secured from other sources evidence he was trying to conceal, his fear or mistrust of the psychiatrist will be increased. The psychiatrist may even decide, after weighing the advantages and disadvantages of filling in the information gap, that more is to be gained by waiting until the patient has developed enough trust to vouchsafe the information on his own. The goal of the social worker's interview, therefore, is not primarily to ferret out every possible fact in a patient's background but to take the kind of history that will contribute to the collaborative effort of the professional team in the way best calculated to strengthen diagnosis, treatment, and eventual disposition.

Value. In child guidance clinics, particularly in cases of young children, most of the preliminary information necessary for a tentative diagnosis is obtained from parents, and the social worker's intake interview is usually the first contact between the clinic and the family. Information obtained at intake may also be valuable for purposes of screening, to determine whether clinic treatment is appropriate for the patient and family or whether a referral to another type of care is indicated. The intake process has been so successful in children's clinics that it has been adapted to adult psychiatric clinics for purposes of screening, preliminary history taking, and explanation of the purpose and mechanics of treatment.

Although a social history is helpful in the understanding of almost any psychiatric illness, it is perhaps more essential in the understanding of childhood conditions, psychoses, character disorders, and marital problems than it is in the understanding of psychoneuroses or psychophysiological disorders.

When hospitalization is a possible plan, a home visit in advance provides valuable information concerning family dynamics and helps the patient make the transition from home to hospital. The social

worker customarily makes visits of this kind, although in some settings one of the psychiatric nurses who will be closely involved in the care of the patient is assigned this responsibility.

The psychiatric diagnosis may not be finally established before treatment begins. In some cases it is an on-going process, subject to constant modification and refinement as treatment progresses and new information becomes available. The social worker usually continues to see the relatives at intervals throughout the period of the patient's treatment.

Group interviews. As psychiatrists have become more concerned with understanding the patterns of interaction among family members as well as the histories of individual family members, they have become more interested in observing families in action. Interviews with the patient and his spouse or with the patient and his parents can give valuable clues about family interaction that are helpful not only in diagnosis but in treatment. When a reluctant family sees that both psychiatrist and social worker participate in the diagnostic interview, they may be more easily persuaded to participate later in active treatment. Furthermore, the casework material that is elicited in a family interview can be more effectively understood by the social worker if he has directly observed the interaction than if he hears about it later from the psychiatrist.

Suggested Cross References

The effects of the environment on behavior are further discussed in Area I, on community psychiatry. For more information regarding the importance of a patient's family on his functioning, see Fleck's section on psychiatry and the family (Section 4.3) in Area B, on the basic behavioral sciences.

12.4 THE MEDICAL EXAMINATION IN PSYCHIATRIC ASSESSMENT

VICTOR F. LIEF, M.D.

When Dr. Robert Felix retired from the office of president of the American Psychiatric Association in May, 1962, he asked psychiatrists to remember how to use a stethoscope. The then director of the Na-

tional Institute of Mental Health was evidently making a plea to his colleagues in psychiatry to remember that they are physicians first and psychiatrists later. His remarks might also be taken to imply that the medical aspects of psychiatry are of major importance.

The well-trained psychiatrist is always aware of the possibility of structural illness in his patient. Any good psychiatric service includes a medical examination as a routine procedure. The same need is present in office practice if the patient is seen before a medical examination has been done.

In dealing with any patient, the psychiatrist can observe him in two ways: (1) the objective way—measuring his blood pressure—and (2) the subjective way—noting what he reports from introspection and trying to understand his display of emotion. The person who asks for help has the need to be understood both subjectively and objectively. The medical examination simply stresses the objective part of the psychiatrist's effort to arrive at a comprehensive diagnosis.

The Medical Examination

Several basic points regarding the medical examination itself are important: (1) Who should do it? (2) When should it be done? (3) How thorough should it be?

Who should do it? Many feel that the psychiatrist should avoid doing the examination if he intends to establish a psychotherapeutic relationship with the patient. They believe that the examination may introduce problems that could disturb this relationship. For example, the neurotic or psychotic patient may well misinterpret a rectal or vaginal examination as a sexual attack. For this reason and because the psychiatrist may have lost some of his medical skills in the process of his specialization, he may well decide to refer the patient routinely to a competent internist. After explaining the need for such expert help, it may be best to leave the choice of physician to the patient.

Of course, if the patient has been referred by a physician or a medical institution, the psychiatrist ought to inquire about the previous findings. This gives him the opportunity to establish a working relationship with the referring doctors, if one has not already been established, and to assess the medical examination in the light of his own findings.

When should it be done? The timing of the medical examination is important. It should be done as soon as possible after the initial psychiatric interview. In the case of the severely depressed patient, it is important to adopt appropriate and effective treatment as soon as possible in order to prevent the possible tragic consequences of delay. With the threat of suicide, treatment in most cases should not be delayed because of possible physical disease.

How thorough should it be? Occasionally, there may be strenuous objections to the medical examina-

tion on the part of the patient due to an irrational fear of physicians or prejudice against them. These feelings must be understood and respected. The presenting emotional symptom may be due to a disease that the patient is unconsciously attempting to hide from himself by denying its existence. After the psychiatrist establishes an empathic relationship with his patient, this reluctance can be tactfully discussed and cooperation for the examination secured. Exhaustive physical tests and special investigations should be performed only when strong indications are present, since they are in themselves a cause of doubt and despondency.

Differential Diagnosis

The accomplished physician in every field is aware that the central nervous system can react to either emotional stress or physical stress by producing similar symptoms. These symptoms can be physiological, psychological, or both. The difficulties in diagnosis arise when a systemic disease in its early stages produces predominant emotional symptoms. Such symptoms may be anxiety, depression, fatigue, lethargy, headache, irritability, dizziness, poor or excessive appetite, drowsiness, or insomnia. The psychiatrist, with his basic medical background as well as his psychiatric skills, is in a unique position to evaluate the findings of the medical examination and to formulate an integrated assessment of the patient.

Behavioral symptoms are often attributed to a psychogenic disorder when in fact they are due to an unrecognized systemic disease. Such a mistaken diagnosis is actually more apt to happen in these days, when the term "psychosomatic" is so popular and comes so readily to the mind of both doctors and laymen. It must be remembered that these behavioral signs and symptoms are manifested or elicited in infectious, toxic, metabolic, degenerative, neoplastic, and nutritional disorders and in some of the anemias.

Any illness that is difficult to identify or understand has a good chance of being labeled as solely psychiatric, particularly if the patient has some obvious emotional disturbance. However, diagnosis in both physical and mental disorders should be made not by exclusion but by positive findings. Trouble in differential diagnosis can result from an "either or" concept: Is the psyche at fault or the soma? In every case, both are involved in varying degrees, and psychopathology and tissue pathology may be present in the same individual. As an example, we note the high incidence of tuberculosis in alcoholism and in schizophrenia.

Exaggeration of personality traits. Personality traits that were present before are often exaggerated in the presence of somatic illness, and the choice of presenting symptom by the patient may be a clue to the underlying personality as well as to the illness. The following case illustrates this.

A 22-year-old single girl, a senior in a well-known woman's college, was seen first by her family physician and then by a psychiatrist. She had an attentive, quick, eager appearance. She had very labile emotions, given to laughing and crying easily. She had been a good student but lately had found it hard to concentrate. At times she seemed anxious and depressed, but at other times she appeared gay and energetic, attending parties and dancing into the early hours. Her appetite was good at all times and often ravenous.

The doctor who saw her initially made the diagnosis of emotional instability and suggested the possibility of the onset of a manic-depressive state. In taking her history, he had not inquired into her sensitivity to heat or cold or about any recent weight loss. He recorded a heart rate of 110 and a blood pressure of 140/70 but attributed this to nervousness. No mention was made of the size of her thyroid. The therapist to whom she was referred saw her three times weekly for 4 months.

After her weight had gone down from 112 pounds to 94 pounds, the psychiatrist's basic medical training asserted itself, and he became suspicious of an underlying thyrotoxicosis. He voiced his suspicion to the referring physician, who then sent her to an internist for a diagnosis. She was found to have an enlarged thyroid, and tests confirmed the presence of thyrotoxicosis.

The psychiatrist's dynamic formulation was that the patient had a conflict; she feared losing her mother and her mother's approval, and then she rebelled against these fears by acting out. It was postulated that she herself was afraid of becoming a mother and accepting a female role.

In order for this correct dynamic formulation to be complete and lead to rational treatment, it had to account for the physiological intervening variable, which was crucial in determining the clinical picture: the overactive thyroid. The key to the complete diagnosis was the discovery of enlargement of the thyroid by careful medical examination and confirmation by laboratory tests. Treatment by radioactive iodine eventually restored the patient to her former state of health and enabled her to complete her college career. Perhaps further psychotherapy was needed, but she did not seek it.

Depression-producing diseases. The insidious onset of malignant, metabolic, or degenerative diseases often results in depression. This has been noted as an early manifestation in a variety of illnesses, particularly those involving the liver. Clinicians have often seen depression in hepatitis and early cirrhosis of the liver. Carcinoma of the pancreas has, on occasion, been particularly hard to diagnose, for psychiatric manifestations tend to cloud the picture in a condition that is so often difficult to diagnose anyway because of the lack of objective signs early in the illness. Adding to the difficulty is the fact that a patient often tends to relate his vague symptoms to psychological factors, especially if he has a prior history of depression.

A 62-year-old married dentist with a good practice became depressed after the death of a favorite child, a married daughter, from carcinoma of the breast. His period of mourning seemed endless. He lost interest in his practice, seemed to lose interest in his wife and remaining daughter, and complained of severe headaches and back pain of gradually increasing severity.

He was examined over the course of 2 years by his family physician, two neurologists, and an orthopedist and was finally referred to a psychiatrist after a thorough work-up in a reputable hospital failed to reveal any structural lesions to account for his symptoms.

His wife was very unhappy because of the change in her husband from an energetic, happy man to a sad, pain-ridden,

apathetic invalid. She was not satisfied with the treatment he had received and finally had him see another internist. The new physician had treated a patient who had depression, backache in the lower dorsal region, and a complete change in personality; that patient had turned out to have a nonobstructing carcinoma of the head of the pancreas.

As a result, the dentist was again admitted to a hospital. The correct diagnosis all too soon became evident. He had lost 30 pounds. He had both abdominal and back pain plus jaundice. An exploratory laparotomy revealed carcinoma of the head of the pancreas with widespread metastases to the liver.

Tests directed toward pancreatic function, examination of duodenal content, and liver scanning for metastases might have made for earlier diagnosis if the possibility of carcinoma of the pancreas had been entertained, thus sparing the patient much unnecessary expenditure of time and money and the shame of regarding himself as a neurotic. The errors made in diagnosis in this case were excusable. Severe depressions in this age group are common, especially in reaction to an object loss. Depressions with somatic symptoms frequently occur. It is the combination of depression plus persistent back pain in the lower dorsal or upper lumbar region that might have aroused the suspicion that there was a lesion in the pancreas and led to its diagnosis.

It may be noted that, in many instances involving disease in an early stage, a routine physical checkup will fail to reveal the pathology. The psychiatrist must remain alert to the possibility of underlying organic illness, especially if psychiatric considerations make an exclusive psychogenic diagnosis unlikely.

Psychosis-producing disease. Toxic psychosis associated with pancreatitis has been studied in alcoholics by Schuster and Iber. The question was whether the symptoms of delirium tremens were due to alcohol withdrawal or to an accompanying illness. Inasmuch as the clinical syndrome of acute hallucinatory psychosis exhibited by 53 per cent of a group of 30 patients with pancreatitis was indistinguishable from delirium tremens, this group was compared with a second group of alcoholics with pneumonia. Only 4 per cent of this group evidenced psychosis, in spite of the fact that fever was higher and the acute illness more severe. The results not only emphasize the frequent occurrence of psychosis in connection with pancreatitis but also suggest that the psychosis is not the result of a nonspecific stress coupled with a background of alcoholism but rather arises from a specific somatic (probably biochemical) disorder in the pancreas. It is postulated that depression may arise from a similar, as yet undetermined, biochemical change in that organ.

Fatigue-producing diseases. Fatigue, which is so often due to psychogenic factors, merits thorough medical investigation. A frequent complaint, fatigue is best defined as a sense of weariness or a lack of feeling of well-being. Other terms with similar connotations are listlessness, lack of energy, lassitude, and weakness. An attempt should be made to distinguish between fatigue and true muscle weakness or asthenia.

The majority of patients who complain of fatigue have no demonstrable abnormality on physical or laboratory examination. There are frequently associ-

ated symptoms of nervousness, irritability, and depression. The fatigue accompanying depression is usually present in the morning and represents a lack of motivation to get going for the day. There is often emotional conflict present in the home or place of employment. These patients are often classified as having reactive depressions or anxiety reactions. Some are called hysterical.

Chronic infectious diseases are the most frequent somatic causes of fatigue. Fatigue is a common complaint early in tuberculosis, subacute bacterial endocarditis, disseminated lupus erythematosus, infectious mononucleosis, infectious hepatitis, chronic pyelonephritis, and brucellosis. Early recognition may be difficult; it is helpful to remember that in these diseases the weariness appears after exertion and usually in the afternoon or evening.

Anemic states are also common causes of fatigue, and the hemoglobin level correlates with the severity of the symptom.

Metabolic causes include hypopituitarism due to the secondary effect on the thyroid and adrenal. Addison's disease and primary hypothyroidism are also causes. Less commonly, hyperfunction of the adrenal, as in Cushing's disease, will cause the feeling. Diabetes mellitus may present fatigue as one of the complaints.

Toxic causes of fatigue are associated with psychological and physical dependency on alcohol, barbiturates, opium and its derivatives, and the large variety of sedatives now widely misused and abused. Bromism, now rare, was once a common cause. Uremic states may also present themselves as fatigue.

The following case, in which fatigue was a prominent symptom, illustrates how a psychiatrist dealt correctly with this problem.

A 26-year-old married secretary came to a psychiatrist because of complaints of fatigue, nervousness, insomnia, depression, and a loss of sexual interest, which plagued her husband more than it did the patient. The psychiatrist referred her to an internist for a thorough medical examination, which involved a painstaking medical history, physical examination, and routine laboratory tests, including a red blood count, hemoglobin, and hematocrit.

The internist determined that she was suffering from an anemia due to intermittent blood loss from bleeding hemorrhoids. For some reason, the patient had paid scant attention to her bowel movements and the occasional discoloration by bright blood. She recalled these symptoms only when specifically questioned about them. Her hemoglobin was found to be 7 gm., and her hematocrit was 30. Surgery and administration of iron for several months renewed her vitality and her interest in work and love.

Suggested Cross References

The behavioral manifestations of organic illness that were mentioned in this section are similar or identical to psychopathological phenomena of psychological origin. These are described in detail in Linn's chapter on psychiatric symptoms (Chapter 13). Sands' section on the psychiatric examination (Section 11.2)

contains a discussion of the methods used to elicit such symptoms.

Chapter 13

Clinical Manifestations of Psychiatric Disorders

13.1 • • •

LOUIS LINN, M.D.

The signs and symptoms of illness, properly collated, form a basis for diagnosis, prognosis, prevention, and treatment.

It used to be said that the best diagnosis is one based on knowledge of etiology. The cure of malaria, for example, depends on chemical destruction of the causative protozoa, and prevention of the disease depends on the elimination of the vector, the anopheles mosquito. On closer scrutiny, even this simple example reveals complexities. South American Indians cured malaria with cinchona bark long before they knew what caused it. To complicate this matter, patients with sickle cell anemia develop immunity to malaria.

Or, consider another example. The tubercle bacillus is surely the cause of active tuberculosis in some, and yet, with the formation of a harmless fibrotic nodule, it can provide lasting immunity in others. Thus, the boundary line between active disease on the one hand and healthy adaptations on the other is not always easily identified. There is, in effect, a continuum between the patient with active disease on the one hand and the healthy, though infected, individual on the other.

The life process in health and disease consists of an ongoing series of adaptations. Depending on their effectiveness, an individual may be healthy and functioning with unimpaired efficiency, or he may be mortally affected by stress, or he may display a number of intermediate reactive patterns representing disease states that are, in effect, the continuations of life in the face of handicaps. Thus, a symptom or even a complex disease process in its entirety may be viewed as a reaction pattern having adaptational significance.

The clinical manifestations of psychiatric disorder are the outcome of complex interacting forces—biological, sociocultural, and psychological (see Figure 1).

Clinical manifestations of psychiatric disorder are essentially expressions of a breakdown in adaptational process. Adaptation from a psychiatric point of view refers to a series of changes that occur within the individual, as a result of which he fulfills his wishes and needs in relation to his personal satisfactions and the realities of his environment. Breakdowns in this process are expressed primarily as abnormalities of thought, feeling, and behavior.

The fact that these abnormalities are the outgrowth of several factors acting in concert has been expressed in the past by such concepts as psychosocial and psychobiological. To express the thesis embodied in Figure 1, one should say that the clinical manifestations of psychiatric disorders are in all instances biopsychosocial. The weight of the biological, psychological, and sociological factors differs from case to case and may vary from day to day in the same case. An accurate prognosis and a rational treatment plan depend on a consideration of all these factors.)

This multifactorial point of view is not embodied in the fixed nosological entities of traditional clinical psychiatry. This section, however, is concerned with each symptom as an adaptation, from essentially normal behavior through a variety of abnormal behavior patterns. It will explore how the patient thinks, feels, and acts; the degree to which he is alert and oriented; how well he observes and remembers. It will discuss his personal eccentricities and the ways he relates to other people in his family, at work, at play, and in the community.

For an understanding of symptom formation, certain additional concepts are useful. For example, there are primary symptoms and secondary symptoms. In schizophrenia, a primary symptom is an irrational fear of others, with withdrawal of interest and activity from the outer world. To reduce his fear further, the patient elaborates a series of rationalizations about the surrounding world; these rationalizations constitute the secondary symptoms of schizophrenia. These become his delusions and hallucinations. As a result of secondary symptom formation, the patient

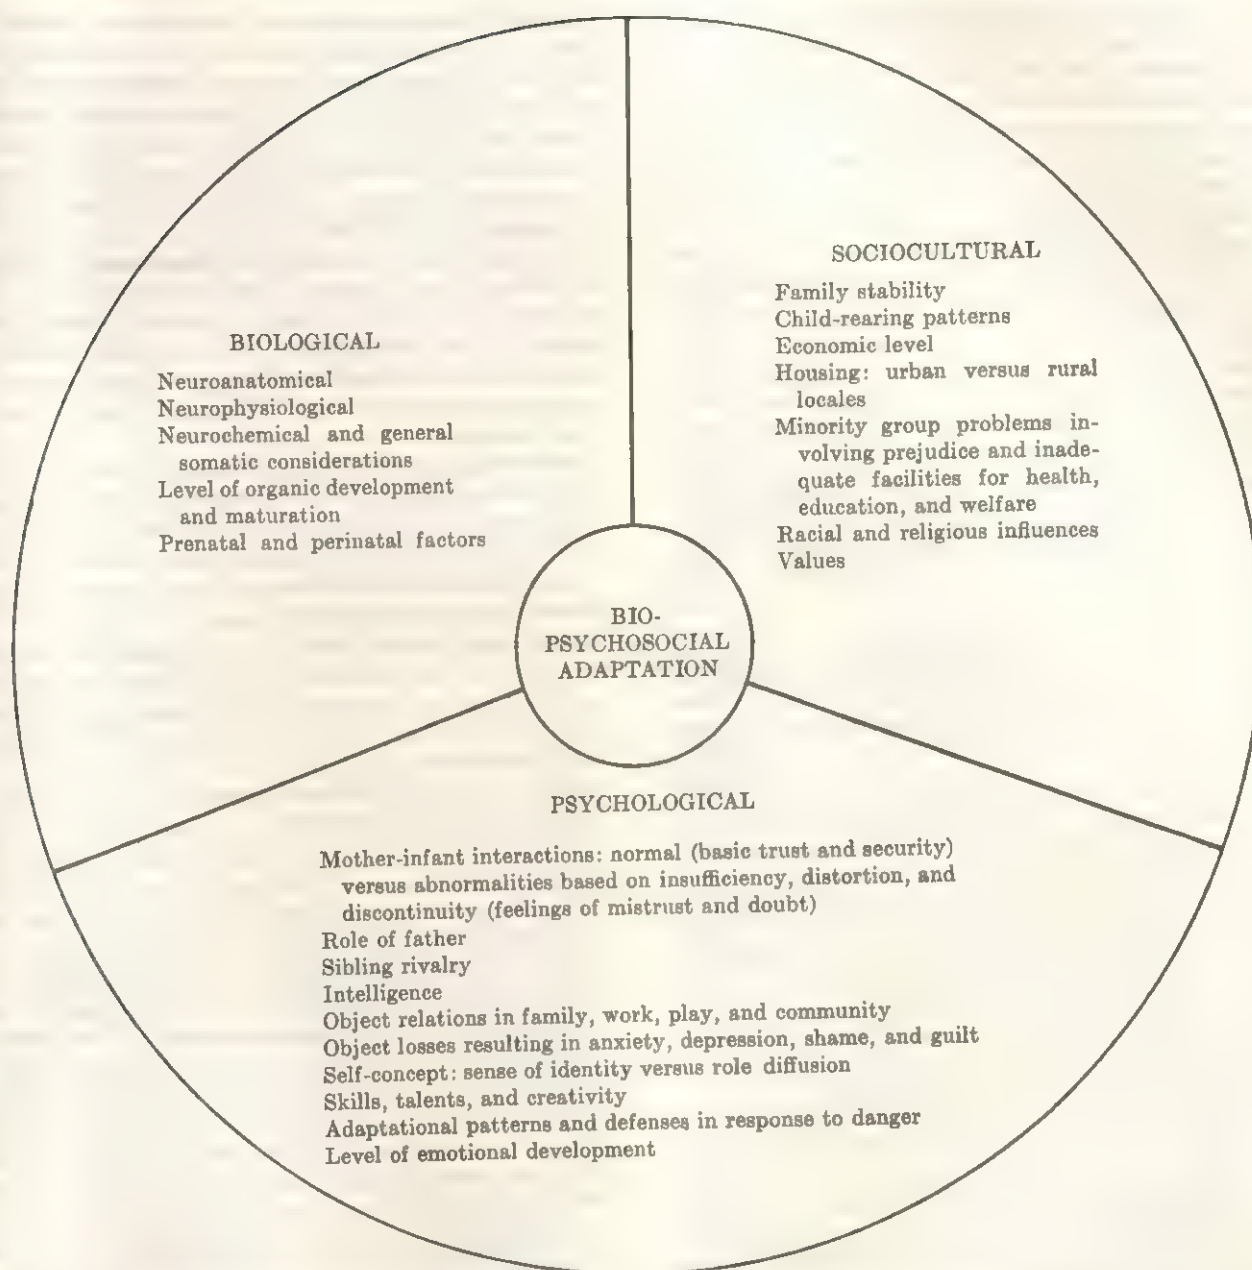

FIGURE 1. Biological, sociocultural, and psychological forces. All these forces interact and affect the psychiatric health of the individual. (Modified after Richmond, J. B., and Lustman, S. L. *J. Med. Educ.*, 29: 23, 1954.)

becomes less fearful of the world, albeit a world that is delusionally distorted.

There are also principal symptoms and accessory symptoms. In a depressed patient, a principal symptom is sadness, with loss of appetite. The accessory symptom may be a peripheral neuropathy based on nutritional deficiency.

There are deficit symptoms and release symptoms. For example, cortical injury may result in a circumscribed aphasic language disorder, which is a deficit symptom. However, if the cortical injury is severe enough, there may be widespread personality changes, which may be interpreted as release phenomena.

Disturbances in Thinking

Normal thought. Thought, or the cognitive experience, includes the processes of judgment, comprehension, memory, and reasoning. It is to be distinguished from conation, which reflects the will or the basic strivings of an individual, as demonstrated by his motoric action and behavior. Normal rational thinking consists of a goal-directed flow of ideas, symbols, and associations initiated by a problem or task and leading to a reality-oriented conclusion.

An individual's flow of ideas becomes available for clinical scrutiny when it is verbalized in speech or

writing. When, in the verbal communication of one's thoughts, a logical sequence of words, sentences, and ideas is followed, the associations are normal. Progression of thought involves the rate and manner of associations and is described as the stream of thought or stream of talk. In thinking, the communicator may be reacting to specific external stimuli or to his physical state, which is a source of internal stimuli. His reaction, in turn, modifies the effect of external stimuli. Or he may be reacting to certain conceptual goals that influence what he says and what he consciously omits.

Normally, the attentive listener is able to follow logically the verbal and ideational sequences of speech. In actuality, a perfectly logical associative flow is rarely observed. Much more commonly, speech sequences are interrupted by the forgetting of a familiar name or fact, a slip of the tongue, a period of relative incoherence during which the thread of the thought is momentarily lost, or a digression that is irrelevant to the main topic.

These lapses from logic (*parapraxes*), which are part of normal thinking, were described by Freud in the *Psychopathology of Everyday Life* as follows: "Slips of the tongue are the best examples of conflicts between strivings for discharge and opposing forces. Some tendency that has been warded off either definitely by repression or by a wish not to express it here and now finds a distorted expression counter to the opposing conscious will." The essence of the *parapraxis*, then, is that it constitutes a compromise or the solution of a problem arising from conflicting psychological drives.

A slip of the tongue (*lapsus linguae*) as an expression of intrapsychic conflict is illustrated by the following. A newspaper editor involved in a feud with the local law enforcement agency stated that in an article that "Mr. X is a *defective* in the police force." An outraged response from Mr. X called forth a brief apology in the next day's paper with the statement, "What I meant to say was that Mr. X is a detective in our police *farce*."

Dreaming represents another normal setting in which lapses from logical thought and expression occur. Although dreams often seem bizarre, meaningless, and illogical, Freud demonstrated that a characteristic organization or pattern of thinking can be identified within the dream. He used the term *primary process* to signify that this pattern of thinking is primary, in the chronological sense that it occurs first in the developmental process. In the primary process, there is a tendency to concreteness, condensation of separate psychological items into one, displacement of feelings from one item to another, and a disregard for time sequences, so that items that are past and items that are present are treated as if they were occurring simultaneously. There is also a considerable use of metaphor and symbolism; that is, one object or idea unconsciously comes to stand for another. According to psychoanalytic theory, all these departures from logical thinking avoid painful feelings and fulfill forbidden pleasures.

Free association may be cited as an example of an artificially induced disturbance in association. In psychoanalytic psychotherapy the patient is requested to

express spontaneously every thought that enters his mind without selection. In effect, he is encouraged to suspend the demands of logic and reality, at least on a purely verbal level, for the duration of the psychotherapeutic session. By this device the normal associative stream is deliberately disrupted and the flow of associations assumes qualities of unpredictability, strangeness, and disconnection with reality.

Disturbances of thought or association. The flow of thought may become seemingly haphazard, purposeless, illogical, confused, incorrect, abrupt, and bizarre. This phenomenon is most conspicuous in schizophrenia. In fact, Bleuler regarded disturbance in association as one of the fundamental symptoms of that disease.

Disturbances in form of thinking. Under this category are included all deviations from rational, logical, goal-directed thinking. Many terms have been used to describe mental activity that deviates from the laws of logic and experience and that fails to take the facts of reality into consideration.

The term *dereism*, or *dereistic thinking*, emphasizes the disconnections that have taken place between the patient's mental processes and his ongoing actual experiences. The mental processes do not follow reality, logic, or experience.

The term *autism* connotes that the forces that distort the flow of associations are derived from within the patient and are in the nature of day-dreams, fantasies, delusions, and hallucinations. Bleuler first coined the term *autism* and later *dereism*, and he used them interchangeably. *Autism* can occur as a character trait, referring to individuals who are bashful, shy, retiring, shut in, inaccessible, or introverted. In its extreme form, *autism* constitutes one of the primary symptoms of schizophrenia. There are two main characteristics of autistic thinking. First, it is less subject to correction by reality than is normal thinking; second, it is much less likely to be followed by action than is normal thinking because it gratifies pathological needs having no relationship to reality.

Early infantile autism is related to *autism* in general by its prevailing quality of extreme withdrawal and absorption with inner thoughts. More specifically, it refers to a form of childhood schizophrenia that is characterized by profound withdrawal and lack of contact from the first years of life, an obsessive demand for sameness in the environment, personalized use of language that is ineffective for communication, and a preference for relationships with inanimate objects. Kanner, who introduced the term, regarded it as a form of behavior resulting from the mother's inability to create a climate of emotional warmth.

Disturbances in stream of thought. Certain abnormalities may be observed in the manner and rate of associative processes.

Neologism refers to the coinage of new words, usually by condensing several other words, each of which have special meaning for the patient. These may occur

within the limits of normal conversation. When used with great frequency in an essentially humorless context, they are characteristic of schizophrenia.

Word salad is a type of speech in which neologisms or incoherent words or phrases that lack logical meaning are used exclusively and in sequence. It is heard most frequently in severe forms of schizophrenia.

Blocking consists of sudden cessations in the flow of thought or speech in the midst of a sentence. Commonly, the patient is unable to explain the reason for the interruption, which is usually due to unconscious emotional factors. When, with conscious effort, the patient endeavors to continue the thought, new ideas may crop up, which neither the patient nor the observer can bring into any connection with the previous stream of thought. The blanking out of the flow of thought, the effort to renew it, and the inability to account for the interruption create an unpleasant feeling within the patient. Blocking is also known as thought deprivation. Although the phenomenon occurs intermittently in normal individuals and in a variety of diagnostic categories, it occurs most often among schizophrenic patients.

The withdrawal from object relations is the first step in the schizophrenic process. As a consequence of withdrawal, the flow of speech may be slowed up or interrupted intermittently in response to inner thoughts and feelings that the patient does not or cannot reveal to the examiner. As he recedes psychologically ever more deeply from the real world, he loses his capacity for abstraction, and his language becomes more concrete. Its logical structure assumes increasingly the patterns of thinking characteristic of childhood or hypothesized for primitive man (archaic speech). He is apt to speak in highly personal symbolism, unintelligible to the examiner or perhaps recognizable only because he uses universal symbols that are understandable cross-culturally. The logical lapses in the associative stream encountered in normal speech as a transient phenomenon may occur more frequently or even constantly in the speech of the schizophrenic patient.

The retreat from the real world is presumed to take place because the world has become objectionable and painful to the patient. As he withdraws his interest (cathexis, libido) from the real world, he may express feelings of emptiness, meaninglessness, and boredom. Having, in a sense, lost the world, he may feel that the world no longer exists (world destruction fantasies), and these ideas may contribute to the flow of his associations.

Alongside the primary drive to withdraw from the real world, there is present in every schizophrenic patient some degree of drive to recontact the world. The latter forms the basis for the secondary or restitutional symptoms of schizophrenia, for example, delusions and hallucinations. The patient now speaks rapidly and animatedly, even though the flow of his speech remains essentially unintelligible to the untrained listener. Thus, the speed of the association stream tends to be reduced during the preliminary stage of withdrawal in schizophrenia and to be speeded up during the restitutional phase, when the schizophrenic is making efforts to recontact the world. However, even in this phase, the intrusion of auditory and visual hallucinations may be abrupt and intermittent. These hallucinations are responsible for the seemingly haphazard and unpredictable nature of the thought disturbance.

Magical thinking, in psychiatry, refers to the belief that specific thoughts, verbalizations, associations, gestures, or postures can in some mystical manner

lead to the fulfillment of certain unreal wishes or to the warding off of certain evils. This type of thinking may occur normally in dreams and in superstitions that are appropriate to a given sociocultural setting. Very young children are particularly prone to this form of thinking as a consequence of their limited understanding of causality. It is a prominent feature in the thinking of obsessive-compulsive patients. It achieves its most extreme expression in the schizophrenic patient.

In his attempt to mollify a threatening world, the schizophrenic patient may use certain words or gestures to control the evil forces. For example, schizophrenic patients may at times believe they are carrying out the most significant work in the universe when actually they are standing rigidly in catatonic stupor.

Intellectualization may be described as a state of brooding or anxious pondering about abstract, theoretical, or philosophical issues. It is a flight into intellectual concepts and words that are emotionally neutral in order to avoid objectionable feelings or impulses. It is commonly used by adolescents in reaction to the powerful sexual impulses that characteristically emerge at this time. It is also seen in obsessive-compulsive neurosis and as a trait of character in certain individuals.

For example, a patient may torment himself with questions like: "What existed before the creation of the world?" "Why is God a man?" "How is immaculate conception possible?" Such questions, couched in religious terms, often conceal thinly disguised sexual issues.

Circumstantiality is a disorder of associations in which too many associated ideas come into consciousness because of too little selective suppression. The circumstantial patient eventually reaches his goal after many digressions. Circumstantiality is to be distinguished from tangential thinking, in which the goal is never reached. In circumstantiality, excessive detail is employed to describe simple events, at times to an absurd or bizarre degree. It may occur as a character trait. Its extreme forms occur in schizophrenia and organic brain disease. Like intellectualization, it often represents a way of avoiding objectionable impulses and feelings.

For example, in response to the question, "Why did you come to the clinic?" a patient responded: "When I got up this morning, I showered and dressed. I was angry at my landlord for not fixing the faucet in my bathroom. I tried to get him on the phone. He wouldn't talk to me. I'll call my lawyer. You see, my rent is supposed to be paid by the Department of Welfare, but they're so nasty. [But why did you come to the clinic?] I'm coming to that, Doctor. You see, they don't care about an upright citizen. I did so much for my community. No one can say I wasn't a hard worker, etc." After repeated questioning, she finally stated she was worried about being constipated.

For the psychiatrist whose task it is to collect much data in little time, the circumstantial patient presents a special problem. A direct verbal assault on this mechanism of defense is apt to be frustrating and futile. It is more fruitful to recognize the underlying anxiety and to relieve it with appropriate psychotherapeutic measures.

A cardiologist complained that many patients exhausted him with trivial details about minor noncardiac complaints whenever he queried them about their heart conditions. He found this behavior particularly exasperating, since he was unable to influence it by cajolery or stern remonstrations. It was explained to him that these patients are fearful and are seeking to postpone as long as possible confronting what they fear most, namely, the possibility of cardiac invalidism or death. By prefacing his crisp inquiry about the patient's cardiac symptoms with a few words of reassurance, he found that such patients very quickly became more cooperative.

Stereotypy is the constant repetition of any speech or action. When this expresses itself as the continuous reiteration of a specific phrase, it is called verbig-eration. It may also occur in the form of writing a given word or phrase over and over again, and it is most often seen in schizophrenia.

Perseveration is the involuntary and morbid repetition of a specific word or idea, which persists in spite of the patient's efforts to move on to a new idea. It occurs particularly following injury to the speech centers of the brain.

For example, a patient with a left hemiplegia following a stroke named a key correctly but then called every other object presented to her during that period of examination a key.

When a patient gives an answer that is in harmony with and appropriate to the question, his answer is said to be relevant. If it is out of harmony, it is said to be irrelevant.

Incoherence is the result of disorderly thinking; thoughts do not follow in logical sequence. Under such circumstances the patient's verbalizations cannot be understood by the listener. A milder manifestation of incoherence is known as scattering.

The rate or speed of verbal production may be accelerated or slowed down. Volubility, or logorhea, is copious speech that may occur more or less within the limits of normal and that is coherent and logical.

Pressure of speech is voluble speech that is difficult for the listener to interrupt. It usually occurs in the context of psychoneurosis as a device for warding off anxiety-provoking questions or as a device for clinging in settings of depression. It may also be a precursor of flight of ideas.

Flight of ideas is a nearly continuous, high speed, flow of speech; the patient leaps rapidly from one topic to another, each topic being more or less meaningfully related to the preceding topic or to adventitious environmental stimuli, but progression of thought is illogical, and the goal is never reached. It is characteristic of acute manic states; hence it is most common in the manic phase of manic-depressive psychosis. The speed and cleverness with which the manic patient leaps from one idea to another can be dazzling. From a qualitative point of view, the manic patient's associations are not strange or absurd. In fact, the connections with identifiable events in the environment are often understandable and even amusing. Puns and witticisms are common.

Clang associations represent a pattern of associa-

tive disturbance in which the mere sound of a word rather than its meaning touches off a new train of thought. It occurs most often in the course of flight of ideas. It may result in a series of punning and rhyming nonsensical associations.

The flight of ideas of a manic patient must be differentiated from the disturbance of association displayed in the rapid speech of a schizophrenic patient in a state of catatonic excitement. The shifts in schizophrenic talk are confused by the indiscriminate overinclusion of material belonging to both shared social contexts and private fantasy contexts. It is the fact that the schizophrenic patient draws largely on an autistic reservoir for his ideas and verbal symbols that makes his productions so strange, as contrasted to those of the manic patient.

In spite of these qualitative differences between the associative stream of the manic patient and the catatonic-excited schizophrenic patient, the absence of a direction or goal for the associative stream is apparent and outstanding in both instances. Both represent a form of flight from the pain of some intolerable external reality, even though one draws on an inner and essentially inaccessible reservoir and the other on an outer and socially evident reservoir for the specific words and ideas that make up the associative flow.

For example, for all the appearance of joy and inner freedom that the manic patient displays, the careful observer can detect the sham. With firm reality-testing intervention, he can break through the mask, even if only for a moment, and reduce the manic patient to sobriety and even to tears.

Furthermore, in almost all clinical instances the differentiation between dependence on so-called inner versus outer resources for the associative flow is not a sharp one. More frequently, the sources of material are mixed, and a differential diagnosis is impossible. Such disorders are called schizo-affective.

In depressed states the flow of association is slowed up, not intermittently in response to hallucinatory or delusional intrusions, as in blocking, but as an ongoing consequence of sadness. The patient thinks and speaks slowly and with great effort. In contrast to the manic patient, he is relatively unresponsive to his environment, and the range of his thoughts is sharply limited. Patients in whom the stream of associations is slowed up or shows retardation may complain of difficulty in thinking. This may be due to difficulty in concentrating on one topic because attention is obsessively preempted by another topic or because the actual flow of associations is sluggish. This difficulty is to be differentiated from mutism, where for conscious or unconscious reasons there is a refusal to speak.

Foreign language patients who are depressed or frightened fall back on their mother tongue and seem incapable of speaking English. As such patients improve, they often surprise their physicians with the amount that they do understand and with the degree to which they can make themselves understood.

It is not enough simply to know a foreign patient's language to establish contact with him. It is also necessary to help him overcome his distrust of the foreign examiner. As this is achieved psychotherapeutically, the patient usually prefers to communicate in the prevailing language of the community.

Brain-injured patients characteristically display

slowing of speech and difficulty with speech, as in aphasia.

Aphasia is a general term for all disturbances of language and communication due to brain lesions but not as the result of faulty innervation of the speech muscles, involvement of the organs of articulation, or general mental or intellectual deficiency. Aphasia results in an inability to pronounce words and names and to indicate the use of common objects. The aphasic disorder occurs following lesions that are essentially localized in the speech centers in the dominant temporal lobe. Aphasias can be divided into motor (or expressive) forms and sensory (or receptive) forms. In the former, understanding is intact, but speech is lost; in the latter, comprehension and object use are lost. Speech impairments due to aphasia typically combine both motor and sensory elements. The difficulties may be on a purely verbal level and involve a disability in the formulation of individual words.

Nominal (amnesic) aphasia represents a difficulty in finding the right name for an object, even though the patient retains the ability to use the object and to describe what it is used for, often through various circumlocutions. It is closely related to the familiar experience within the limits of normal behavior of not being able to recall the name of a person or object at a time when one is able to describe many details concerning the object or person in question. In its mildest forms it may be seen in fatigue, anxiety, and alcoholic intoxication. It is more marked in senile dementia and in brain lesions involving the temporal lobe of the dominant hemisphere.

Syntactical aphasia is the inability to arrange words in proper sequence. The subject is usually aware that the word arrangement is wrong, even though he is helpless to correct it.

Semantic aphasia is the inability to recognize the full significance of words. It is related to a loss in the capacity for abstract thinking.

Jargon aphasia is a type of aphasia in which speech is reduced to a limited group of unintelligible neologisms, which the subject uses in a stereotyped fashion.

In aphasic disorders, the patient is usually alert. He is self-conscious about his errors and for this reason is often reluctant to speak. This is particularly true of patients whose premorbid personality included a great concern for orderliness and an inability to tolerate imperfections. Such aphasic patients tend to be depressed and withdrawn.

Catastrophic behavior is the term used by Goldstein to characterize the acute reactions of agitation, panic, and intensification of neurological defect that brain-injured patients show when they are pushed into performing simple tasks they can no longer do. Perseveration, mentioned earlier, is a device for warding off catastrophic behavior by clinging to a specific response with which the patient feels comfortable.

Disturbances in content of thought. Here again, the flow of ideas becomes available for clinical scru-

tiny only when verbalized in speech or in writing. And yet, certain types of thought content are essentially nonverbal.

Nonverbal thought content is encountered primarily in certain states of ecstasy or mysticism. In otherwise normal individuals, these feelings may occur fleetingly during the induction phase of general anesthesia. They may be chemically induced in addicts. They may also occur transiently in schizophrenia. In each instance the patient emphasizes that his thoughts are essentially inexpressible.

With the appearance of language in the developmental process, thought content of increasing complexity makes its appearance.

From a developmental point of view, concrete thinking, which involves specific objects or creatures, things, and phenomena, as distinguished from qualities or other attributes one can ascribe only to classes of objects, creatures, etc., appears first in early childhood. The capacity for abstract thinking, characterized by symbols that cannot be directly perceived through the senses, develops later, but probably earlier than was previously suspected. However, considerable verbal skill is needed to communicate abstract ideas; therefore, in their overt expressions at least, abstract thinking does not appear definitely until adolescence; it appears increasingly thereafter as verbal skills are developed.

In schizophrenia, verbal production often tends toward concreteness. Psychological tests devised to measure abstract thinking, such as the ability to interpret standard proverbs, show impairment in many schizophrenic patients. Goldstein emphasized the role of impaired abstract thinking in the language impairments of brain-injured patients.

A fantasy is a mental representation of a scene or occurrence that is recognized as unreal but is either expected or hoped for. There are two types of fantasy: creative fantasy, which prepares for some later action, and day-dreaming fantasy, which is the refuge for wishes that cannot be fulfilled.

Creative fantasy may start in inspirational moments that are deeply rooted in unconscious factors. However, it is then elaborated systematically and is translated into a realistic program of action.

The day-dream as a refuge for wishes that cannot be fulfilled is an almost self-explanatory category. It tends to be diminished with psychological and biological maturation. Increasingly, day-dreaming is replaced by direct sexual satisfaction with an appropriate love object and by sublimation at work and at play. Sublimation is the substitution of satisfying guilt-free and anxiety-free activities for those that previously generated guilt and anxiety.

To some extent day-dreaming persists within normal limits throughout life. However, in autistic characters and in borderline psychotic states, day-dreaming may preempt so much time and energy that it seriously impairs the individual's capacity for normal relationships and responsibilities.

Pseudologia fantastica differs from normal day-dreaming in that the subject believes in the reality of his fantasies intermittently and for long enough intervals of time to act on them.

Patients displaying this symptom are often referred to as pathological liars. They often outrage the moral sensibilities of the victims of their fantasies and commonly provoke punitive responses. These responses are reinforced by the fact that

the patient acknowledges the falsehood of his statements when confronted with conflicting evidence. However, these patients have a compulsive need to act out these fantasies repeatedly. This is apparently a response to a pathological need for self-deception, with a resistance to correction. It is often difficult to ascertain whether the untruths are expressed with unconscious intent to deceive or as part of a pathological and even delusional distortion of reality.

The imposter is a type of pathological liar who seeks to gain some advantage by imposing on others various lies about his attainments, social position, or worldly possessions.

The imposter is obviously suffering from a severe identity problem. He is attempting to foist a false identity on society, but perhaps of greater significance is his need to reject his real identity for unconscious neurotic reasons. Such individuals are often quite gifted and are often capable of success in the real world, but an unconscious fear of success causes them to mispend their talents. They tend to be self-defeating in their dramatizations and usually end up with humiliation and punishment.

A **phobia** is an exaggerated and invariably pathological dread of some specific type of stimulus or situation. Table I presents a list of the most common types. Many other phobias have been described, and they are probably limitless in number.

The basic mechanism involved in a phobia is a reaction of anxiety in a setting in which a person would normally experience sexual excitement or rage. Various disturbances in thought content represent efforts to diminish this anxiety. At times the associative connections seem relatively direct. A forbidden wish to suck, bite, or devour, for example, may result in a fear of eating specific foods or a fear of eating in specific places. A fear of loss of control of violent impulses may lead to a fear of all scenes of violence. A fear of being cut or stabbed may lead to a fear of contact with sharp instruments. In other instances the associative connections have become obscured. A

fear of walking on the street (agoraphobia), for example, may be based on unconscious prostitution fantasies. The sexual excitement and the fear of punishment connected with the latter may result in palpitation and breathlessness, which then presents clinically as a cardiac neurosis. Most often, the phobia for which the patient seeks treatment is like the manifest content of a dream. Behind the expressed fear is a chain of other fears. And entwined in the very fears supposed to guard against forbidden impulses are thoughts, feelings, and actions that secretly fulfill those very forbidden impulses (return of the repressed).

For example, a pretty young married woman, mother of a daughter aged five, became pregnant. She was aborted illegally at her husband's behest. When the abortionist let her see the bottle containing the curetted fetal tissue, she experienced a sharp pain in her eyes. Thereafter, she was afraid to go out into the street because of a fear that a foreign body would fly into her eyes. Psychoanalysis showed that this was a displacement from below upward. That is, her eye fear concealed a fear that she would be impregnated as a result of prostitution fantasies. The latter were the result of rage against her husband (whom, incidentally, she identified with her punitive mother) for not permitting her to have a baby. When she did venture out into the street (and she did so very often), she would experience a foreign body sensation in her eye, which would send her flying in a panic to her family doctor, who lived nearby. The family doctor's search for the foreign body was regularly associated with much fluttering of eyelashes, fearful breathing and struggling, all of which resulted in her seducing her doctor into sexual play, consisting mostly of kissing and caressing. Since she unconsciously identified her family doctor with her father, this sex play represented a revival of her childhood attachment to her overly demonstrative father. As a result, it aroused much guilt and anxiety, as well as sexual excitement.

An **obsession** is the pathological presence of a persistent and irresistible thought, feeling, or impulse that cannot be eliminated from consciousness by any logical effort. Obsessions may be experienced within normal limits as transitory thoughts that do not interfere substantially with the adequate performance of one's mental functions and that can be minimized or eliminated by actively concentrating on other objects. Obsessions as symptoms of obsessive-compulsive neurosis, on the other hand, control and plague the individual more or less constantly, compelling him to carry out specific ritualized or stereotyped acts, known as compulsions, in order to minimize their distressing effects. There are intellectual obsessions, in which the individual is constantly preoccupied with one or more pseudophilosophical questions. There are also obsessive fears and doubts that overlap the phobias.

Whereas the phobic or hysteric patient dramatizes fantasies in the form of relatively simple fears and bodily sensations, the fantasies of the obsessional neurotic are converted into defenses that are largely verbal, intellectual, and complex. Words and thoughts are invested with unrealistic power. An inadvertent thought or comment, it is imagined, may cause great harm to a loved one or punishment to one's self. By the same token, a given verbal formula may ward off danger to self and to others. Since words are so powerful, it becomes necessary to choose one's words carefully. And for the obsessional neurotic, no matter how carefully he chooses his words, he is never sure that he chose carefully enough, and so he repeats himself with verbal formulae of ever increasing complexity. Behind this preoccupation with seemingly magical but actually trivial words is concealed an intrapsychic struggle involving erotic and ag-

TABLE I
Phobias*

Phobia	Dread of	Phobia	Dread of
Acro-	High places	Nycto-	Darkness, night
Agora-	Open places	Patho- (noso-)	Disease, suffering
Algo-	Pain	Peccato-	Sinning
Astra- (as- trapo-)	Thunder and lightning	Phono-	Speaking aloud
Claustro-	Closed (confined) places	Photo-	Strong light
Copro-	Excreta	Sito-	Eating
Hemato-	Sight of blood	Tapho-	Being buried alive
Hydro-	Water	Thanato-	Death
Lalo- (glosso-)	Speaking	Toxo-	Being poisoned
Myso-	Dirt, contamination	Xeno-	Strangers
Necro-	Dead bodies	Zoo-	Animals

* Modified from Warren, H. C. *Dictionary of Psychology*. Houghton Mifflin, New York, 1934.

gressive impulses in every conceivable combination of activity and passivity, of masculinity and femininity, of piety and blasphemy, of obedience and rebellion. Such verbal gymnastics demand a great mastery of language. The latter, in turn, requires considerable intelligence. Conversely, whenever verbal skills are limited because of limitations of intelligence or education, obsessional defenses usually do not appear.

It is not at all rare for patients with phobias and obsessions to function in an outwardly normal fashion and to maintain full awareness of the irrational nature of their thoughts; that is, the symptoms are ego-alien or ego-dystonic (repugnant to the ego of the patient), and he has insight into the irrational nature of his thoughts. The ego-alien attitude toward symptoms combined with the capacity to maintain a fairly full range of real object relations are characteristic of the psychoneuroses. However, ego-syntonic symptoms, that is, acceptable to the ego, can occur within the framework of psychoneurosis, particularly in the types in which the differential diagnosis between psychoneurosis and psychosis is difficult to make. Whether one measures the degree to which real object relations are retained or the degree to which symptoms are ego-alien, there is a continuum between normal, psychoneurosis, and psychosis.

A patient may seem to retain a completely ego-alien attitude toward phobic or obsessive symptoms but be so withdrawn from the world of real objects that a psychotic diagnosis is warranted. The fact that such psychotic patients present essentially psychoneurotic symptoms has led to the diagnostic description pseudoneurotic schizophrenia. Similarly, there is a continuum in the degree to which symptoms are experienced as ego-alien. Day-dreams and phobias within the limits of psychoneurosis may shift over into the category of psychosis, with hallucinations and delusions, by a simple increase in the intensity of the experience.

When thought content centers around a particular idea and is associated with a strong affective tone, it is said to be dominated by a trend or preoccupation. Such excessively charged ideas are said to be overdetermined in that they are caused by the confluence of multiple conflicts and drives, all of which carry great affective weight and meaning.

A preoccupation or an overdetermined idea may lead to an obsession. At other times it may become the basis for an idea of reference if projection occurs, as when a person attributes to neutral remarks and incidents direct references to himself. Projections form the basis of paranoid or oversuspicious thinking. This form of thinking may occur more or less within normal limits in early childhood, when the youngster is self-centered and insecure. When a shy but essentially normal person enters into a social situation, he may experience a series of self-observing, self-criticizing thoughts, which he succeeds in brushing aside in favor of the social satisfactions open to him. Such thoughts, if intensified to the point of paralyzing discomfort but recognized as ego-alien, may then be described as neurotic hypersensitivity. The latter expresses itself as extreme shyness and in autistic tendencies.

A delusion is a false belief that arises without appropriate external stimulation and that is maintained more or less unshakably and fixedly in the face of reason. Furthermore, the belief held is not one ordinarily shared by other members of the patient's socio-cultural and educational group. For example, it is not a commonly believed superstition or a religious or po-

litical conviction. Delusions are pathognomonic of the psychoses. They occur most frequently in schizophrenia, but they can be observed in all psychotic states, including those of organic origin. A delusion represents an autoplasmic response, whereby one adapts by altering the intrapsychic milieu, as opposed to the alloplasmic response of the reality-oriented individual, who adapts by altering his environment.

Freud's well known Schreber case is an example of projection. Freud observed that homosexual impulses, which were unacceptable to Schreber, underwent a series of transformations. Schreber first declared that he did not really love his homosexual object but hated him. In a still further development of his thought disturbance, Schreber declared that he did not hate his love object but rather that he himself was the object of that hatred. Thus, the unconsciously loved homosexual object emerged finally into consciousness as Schreber's persecutor.

The following case illustrates ideas of reference and paranoid delusions. A married man, aged 58, with a life history of dependable, conscientious work as a bookkeeper, became sleepless, anxious, and unable to concentrate. He developed the belief that his vision was failing because of poisons secretly placed in his food by former neighbors. He found a misprint in a newspaper that he felt was placed there by the editor to shame him publicly. Admitted to the psychiatric service of a general hospital, he said that cars passing up and down the street contained agents who were spying on him. He believed that the electric light bulbs in his room were emanating a purifying radiation to counteract syphilitic germs, which he was supposedly breathing into the atmosphere, although a physical examination was negative for syphilis. He was diagnosed as having involutional psychosis with paranoid and depressive features.

In some delusional states, persecutory feelings arise within the patient's body, as intestinal movements or the sensation of the stool in the rectum. Preoccupation with body feelings may result in a variety of somatic delusions that, in the schizophrenic, are characterized by a quality of strangeness. They differ in this respect from the localized somatic symptoms of hysterics and the generalized physical complaints of hypochondriacs.

In other delusional states, sexual feelings are attributed to a distantly located influencing machine operated by a persecutor. The patient may claim that this machine compels him to see pictures, forces certain thoughts and feelings on him, or abruptly drains off all thoughts and feelings. He may attribute to the machine erections, cutaneous eruptions, etc. The delusion of the influencing machine appears as a relatively late elaboration in schizophrenic thinking and seems to originate in the patient's need for causality. The description of the influencing machine by psychotic patients necessarily draws on the cultural and technological sophistication of the patient.

Pathological jealousy may occur in marital settings in which a spouse has unconscious extramarital sexual impulses, either heterosexual or homosexual, which are then projected onto the marital partner and emerge clinically as delusions of infidelity.

Litigiousness is a pathological tendency to take legal action because of suspected and imagined persecution. When these imagined persecutions reach de-

lusional proportions, we speak of delusions of persecution. Legal action may be brought against a surgeon, for example, because of delusional misconceptions the patient harbors about a surgical procedure. Relatives of a hospitalized patient may have litigious attitudes toward the professional staff of the hospital because of their own hostility toward the patient, which is then projected onto the staff. ("It is not I who wants to be rid of this patient. The doctors and nurses have these feelings.")

The thought content encountered clinically is determined, among other things, by the patient's mood. The ecstatic states referred to earlier may be associated with delusions of grandeur, which means a delusional exaggerated idea of one's importance. The male patient may express the idea that he is the Saviour or a latter day saint; the female patient may believe she is the Virgin Mary and is about to give birth to the Baby Jesus. The delusions of grandeur may result in identifications with political or military figures of great power. The salvation of the world is the basic delusional goal. Often this grandiose goal is to compensate for feelings of inadequacy. In manic states there may be inappropriate delusions of great wealth that result in crippling financial expenditures.

A shift of mood from elation to depression may result in the delusion of having committed an unpardonable sin. This is usually associated with guilt and may result in a delusion of self-accusation, characterized by intense remorse. In place of the delusions of saving the world, there may appear the end of the world fantasy. The patient may believe that the salvation of the world depends on his own death, and he may destroy himself or seriously mutilate himself to save the world. (In less bizarre terms, the depressed patient may feel that the world would be better off without him and have suicidal impulses or ideation on an altruistic basis.) In contrast to the delusion of great wealth, there may be, in the depressed state, a delusion of poverty. The complaint, "I am poor," is characteristic of depression, almost independently of the patient's true economic condition. In addition to feelings of guilt, worthlessness, and poverty, the patient may express a loss of interest in all previously satisfying spheres of activity. He may lose his appetite for food, family, sex, work, and play. Loss of appetite for food may be the result of delusions of poisoning, as a result of which he doesn't eat, to the point of losing much weight. Paradoxically, some patients invest the process of *not* eating with intense emotional satisfaction, as a result of which they lapse into an anorexia nervosa which, on occasion, may lead to death by starvation in spite of an apparent continued interest in other aspects of life.

In considering the disorders of thought content, one must take into account the *intent* of the verbal production as well as the content. As a result primarily of depression and anxiety, many patients have a desperate need for the company and attention of the

therapist. In return for his attention, these patients are motivated to say almost anything calculated to engage his interest. Is the therapist interested in dreams? Then the patient will dwell on dreams. Is he interested in infantile sexuality, in orality, in the castration complex? In each instance, the patient tunes in on the therapist's special interest. He responds to subtle cues almost telepathically. Such patients often seem to prove almost any theory that the therapist cherishes (doctrinal compliance). For the beginner in psychotherapy, the flood of associations provided by such patients can be an endless source of interest and yet prove, in the long run, to be of questionable psychotherapeutic value. It often takes great clinical skill to differentiate between content offered essentially for purposes of clinging and content that can be used to increase self-understanding and motivate clinical change.

Just as the content of associations may be rendered interesting by a patient who wished to please the therapist, so may the content be rendered boring or irritating by a fearful patient who wishes to keep the therapist at a safe distance. The beginner in psychotherapy may fail to understand the unpleasant feelings that such a patient arouses in him and may reject him, erroneously, as an "uninteresting" case. Whether the intent is to draw the therapist closer or to repel him, the actual content of the verbal productions in such instances is of secondary importance.

A patient who has withdrawn from normal object relations will often express this withdrawal by an unusual choice of words in his conversation. The flow of associations may be coherent and relevant, and the actual word choice correct from the point of view of dictionary meaning, yet an overtone of stiltedness, based on too personalized a vocabulary, may provide a subtle clue to clinically significant psychopathology. For example, when asked the function of the heart, a schizophrenic patient answered, "It invigorates the blood by putting red and white corpuscles in the blood stream." When asked how yeast causes dough to rise, another schizophrenic patient answered: "Something takes place in the bacteriological context. When heat is applied, molecules become active and cause it to rise."

When a patient seems slow witted and dull, there may be an emptiness of content based on mental deficiency. Where this is suspected, confirmation by formal psychological testing is mandatory.

Disturbance in thought content in brain-injured patients.

To understand the disturbances of association and thought content seen in patients with widespread (as contrasted to focal) organic brain disease, one must turn to certain theoretical considerations.

Most hospitalized patients suffering from a serious physical impairment of any kind wish to be well and wish to go home. Most such patients accept the realities of the illness and the necessary for hospitalization and make an adaptation based on premorbid personality.

The patient with widespread brain injury presents a different

picture. In many ways he acts like a person in a waking dream. Is there a wish to be out of the hospital? Then the patient speaks and acts as if he were not in a hospital. Is there a wish to be well? Then, for these brain-injured patients, wishing makes it so, and they display the syndrome of anosognosia, the denial that physical illness is present. A blind person insists that he can see, and a paralyzed patient says that he can walk. Some patients deny the major illness and ascribe the need for hospitalization to a trivial illness or to a previous illness from which the patient has long since recovered. A patient who has just had a craniotomy, for example, may insist that all he had was a tonsillectomy or an appendectomy. On occasion, a patient admits that he cannot move a paralyzed leg but rationalizes this as the result of fatigue or laziness. A patient with a paralyzed limb may disown the incapacitated extremity by saying that it belongs to someone else or that a paralyzed arm is lying on a bedside table "like a set of false teeth." When questioned about their own illness, some anosognosic patients respond by discussing the illness of some other member of the family; others (still paralyzed) agree that they had a hemiplegia in the past but are fully recovered at this time. Blind patients give detailed descriptions of objects they are "looking" at; others alter the name of the hospital in a way to deny its medical function or to move it closer to home or business. They fill in memory gaps with extensive confabulations, the common denominator of which is the absence of physical disability.

In reduplication the patient acknowledges that he is in a hospital but insists that it is a good hospital compared with one with the identical name nearby. A patient may acknowledge that a right arm is paralyzed but insist that there is an extra right arm that is not paralyzed. The anosognosic patient may be mute and unresponsive when questioned by a physician and yet speak freely to a relative.

Anosognosic patients may show a language disorder called paraphasia, the use of word substitutes. In paraphasia, responses to questions are not particularly slowed up as they are in aphasia. The paraphasic abnormality occurs much more frequently in relation to hospital (or disease-connected) words. When a word is produced, it is usually a neologism or an inappropriate word that tends to deny illness. For example, a clinical thermometer is called a "gradient"; a wheelchair is a "chaise." At times, anosognosic patients speak of themselves in the third person. In response to a query about surgery already performed, a patient answered, "He did not have an operation." A paralyzed limb may be referred to as "he," "she," or "it," as if to disclaim possession of the sick part. A question about a personal disability may be followed by a detailed discussion of an illness suffered by some other member of the family. The patient may launch willingly into a discussion of some minor ailment while steadfastly refusing to discuss the major reason for hospitalization.

Other language patterns seen in anosognosic patients include intellectualization and the liberal use of clichés as facile platitudes available to the patient with the expenditure of little thought or energy. Characteristic of anosognosic patients is the fact that they do not alter their basic errors in spite of repeated corrections by the examiner.

In purely quantitative terms, the success with which the brain-damaged patient succeeds in denying his illness is determined to some degree by the extent of the brain disease. In acute reversible brain disease, the period of maximal brain damage is associated with equanimity or euphoria. In the euphoric stage, even the patient's speech may resemble that of a mild hypomanic reaction. However, the humor (*Witzelsucht*) is characteristically shallow, and the range of ideas is sharply circumscribed. It is a type of facetiousness with a tendency to punning. In intermediate stages of brain damage, the flow of associations tends to show a paranoid trend, although again with a relatively limited ideational content. With further improvement in brain function, the entire capacity for denial of illness may dissolve. At this point a depressive reaction, not en-

tirely inappropriate to the clinical realities, may emerge. The slowed up flow of associations then reflects this affective state.

When a barbiturate, such as Amobarbital sodium, is injected intravenously into a depressed and no longer anosognosic brain-injured patient so that he shows nystagmus and slurring of speech, all the previously noted association patterns characteristic of denial of illness can be temporarily reestablished. This fact has formed the basis for a presumptive test of organic brain disease.

The manic and paranoid states seen in brain-injured patients have a certain stability that resist correction. However, during the transitions from one level of somatopsychic organization to another, there are intervening stages during which terror predominates and the flow of associations is maximally disorganized. The picture seen then is one of delirium and in many ways is comparable to the withdrawal reaction seen whenever a patient who has maintained some form of psychosocial adaptation with the help of a drug is suddenly called upon to readapt to his environment without the help of the drug.

It is thus possible to see in a single patient all the clinical manifestations that at one time or another have been associated with organic brain disease. The basic and fixed element in the clinical picture is the premorbid personality of the patient. The variables derive from the location, extent, and severity of the brain lesion.

Since the fact of brain damage impairs the availability of language and ideas, anosognosic patients tend to lack verbal and ideational complexity in their associations. Nevertheless, the delusional fulfillment of the wish to be well draws into its train wishful fulfillments from other layers in the emotional development, exactly as take place in a dream. The content of the clinical picture becomes more complicated as a consequence, but the wish to be well remains.

Disturbances in judgment. Judgment, from a psychiatric point of view, is the mental act of comparing or evaluating alternatives within the framework of a given set of values for the purpose of deciding on a course of action. The comparison may be in terms of magnitude, rightness, goodness, beauty, or economic worth. If the course of action decided on is consonant with reality as measured by mature adult standards, the judgment is intact, good, or normal. If, on the other hand, the course of action is inconsistent with reality, the judgment is impaired, poor, or abnormal.

The capacity to decide whether or not to take action depends on the capacity to think, that is, to anticipate the future in the imagination. This, in turn, depends on the capacity to bring before the mind once again something that has been previously perceived, to reproduce an object in the imagination without requiring the actual presence of the object. The imagined or internalized representation of an object is not always a faithful one. It may be modified by omissions or changed as a result of merging elements. Reality testing determines how far such distortions have gone.

The thought process involved in reality testing takes time. Freud described thinking as "experimental action." It begins with a tentative sampling of data from the outer world; these data are then compared with data from the reservoir of stored memories. This process culminates in a decision, which puts an end to the postponement of action. *Thus, the controlled postponement of action is the essence of judgment.* The person with good judgment looks before he leaps. But judgment leads from thought to action. Reality testing makes it possible to try out actively and in small dosage an experience that may be traumatic if permitted to happen passively and in unknown dosage.

The ability to recognize, love, and fear reality begins long before speech is learned. The infant becomes aware of reality as represented by the human face at approximately 3 months of

age. The infant reacts reflexively to the sight of the human face with a smile. At about 8 months of age, the infant begins to compare and evaluate human faces. He learns to differentiate the face of the mother from all others. The infant reacts with love to her face and with fear and anger to others. Psychoanalytically, it is hypothesized that the infant takes in her face with its eyes and eagerly swallows her food. It turns away from others and expels the food offered by these strangers as bad objects. These simple nonverbal relationships provide the model for the process of judgment—paying attention, comparing, evaluating, decision making, and action.

Speech initiates a decisive step in the development of reality testing and judgment. Words permit more precise communication and more precise anticipations of trial actions.

Thus far, the issues are quite clear. The function of judgment then depends on maturation of the mental apparatus. Intelligence and education are required for the inculcation of values.

Intelligence has been defined as the capacity to meet a novel situation by improvising a novel adaptive response. This capacity is composed of three factors: abstract intelligence, which is the capacity to understand and manage abstract ideas and symbols; mechanical intelligence, which is the capacity to understand, invent, and manage mechanisms; and social intelligence, which is the capacity to act reasonably and wisely in human relations and social affairs.

For good judgment to prevail, the sensory apparatus must be capable of accurate perception and discrimination. Memory must provide a reservoir of data as a basis for comparison. The motor apparatus must have the skills to carry out decisions and the inhibitory mechanisms for postponing action. Thus, a developmental process is automatically implied in the very concept of judgment. Although rudimentary manifestations of judgment can be found in infancy and early childhood, judgment develops steadily with biopsychosocial maturation. It is maximal in the fully alert, emotionally mature adult. It is impaired in all circumstances associated with regression.

If judgment is a mental function calculated to insure reality-oriented action, then mental states that avoid painful reality are inevitably associated with impairment of judgment. These may occur transiently in relation to parapraxes. A suspension of logical judgment is characteristic of dreams. Impaired judgment is a regular accompaniment of all psychotic states.

Adolescents display impaired judgment for many reasons. Through lack of education and experience, they may fail to recognize which situations or ideas merit attention. Adolescence, with its characteristic intensification of intrapsychic conflict, may be associated one moment with excellent reality testing based on adult goals and aspirations and a moment later with impaired reality testing based on persistent, unmastered infantile longings. Undeveloped values and self-discipline may precipitate ill advised actions. Thus, judgment in the adolescent is notoriously uneven and unpredictable.

Estimates of judgment may be based on responses to test questions or standard hypothetical situations. For example, a mentally defective subject with a long history of delinquency and fire-setting was asked, "What would you do if you found a stamped, addressed, and sealed envelope in the street?" He answered, "I would put it in the mailbox if it didn't have anything in it for me." Wechsler has observed

that a significantly higher score in the performance scale over that in the verbal scale of the Wechsler Adult Intelligence Scale is suggestive of the character disorders associated with impairment of judgment.

Disorders of Consciousness

Consciousness has been defined as the distinguishing feature of mental life. It is synonymous with the quality of being aware and of having knowledge. Thus, it is a faculty of perception that draws on information from the outer world directly through the sense organs and indirectly through stored memory traces. Implicit in the concept of full consciousness is the capacity to understand this information and to use it effectively to influence the relationship of the self to the environment. Consciousness may be said to have a sensory component or degree of receptive awareness, which is measured as cognitive intensity, and a motor component or degree of kinesthetic readiness to initiate and execute a voluntary act, which is conative intensity.

Levels of consciousness. Consciousness exists on a continuum, with maximum alertness at one extreme and absolute unconsciousness or coma on the other; in between are confusion, clouding of consciousness, delirium, and stupor.

In confusion there is disorientation as to time, place, and person and a feeling of bewilderment. It is often accompanied by an impairment of consciousness and is encountered both in organic states and functional disorders.

In clouding of consciousness there is a disturbance in perception, attention, and thought, and a subsequent amnesia.

Delirium is a psychic state characterized by disorientation in all spheres, confusion, clouding of consciousness, and bewilderment in association with anxiety, fear, illusions, and hallucinations. It is the result of an infection, tumor, hemorrhage, or toxic-metabolic disorder and is classically associated with acute brain syndromes.

Stupor is a state of relative nonresponsiveness to the environment. It differs from the total insensibility of coma in purely quantitative terms. Stupor can occur as a lesser stage of impaired consciousness in all the conditions causing coma. However, there are, in addition, psychogenic stupors, in which the patient is motionless, mute, and more or less nonresponsive to powerful stimuli but without organic brain disease or impairment of reflexes. In catatonic stupor, for example, the patient is aware of his surroundings but is intensely preoccupied. He is able to give a relatively full description of the happenings in his environment in retrospective accounts after the catatonic stupor has subsided. Patients who exhibit the basic symptoms of manic-depressive psychosis may present a picture of stupor instead of depression. Because of the reportedly better prognosis in these cases, these patients are said to exhibit benign stupor.

Coma is the term describing the most profound degree of unconsciousness, in which there is no detectable evidence of responsiveness. At its deepest levels, even reflex responses to painful stimuli and to breathing obstructions are abolished. Function is reduced to the mere vegetative persistence of circulation and respiration. Coma may be the result of diffuse inflammatory brain disease (encephalitis), vascular disease (intracranial hemorrhage, thrombosis, or embolism), brain tumor, poisoning, or factors of toxic-metabolic origin.

Coma vigil is a coma in which the eyes remain open. This condition may occur in a variety of acute organic brain disorders, particularly when the diencephalon is affected. On occasion, patients in coma vigil follow the human face with their eyes when they are responsive to no other stimuli. In such instances, tracking movements of the eyes can be elicited by means of a two-dimensional pictorial representation of the face as well as the actual face itself.

This curious phenomenon seems to represent a regression to a stage in development during the 1st year of life, when the infant fixes his gaze on the face of the mother during feeding.

Attention. Attention is an aspect of consciousness that relates to the amount of effort exerted in focusing on certain portions of an experience so that they become relatively more vivid. One may speak of primary attention, which is passive, involuntary, automatic, instinctive, or reflexive, and secondary attention, which is active or voluntary.

Attention in both its primary and secondary aspects may fluctuate in intensity from moment to moment in acute brain disorders, such as subdural hematoma and impending diabetic coma. Attention may remain basically alert and vigilant yet shift swiftly from topic to topic. In distractibility an individual's attention is too easily drawn away from a given content by extraneous or distracting stimuli. Although a certain amount of distractibility is normally present, it occurs in its extreme form in the manic state. Distracting stimuli may arise not only from the outer environment but from inner fantasies as well. The latter are present in the psychoneuroses and may play an important role in learning disability. They are also outstanding features in schizophrenia.

Attention span is measured by the length of time that an individual can apply himself to a given task. It is, in a sense, the reciprocal of distractibility. Attentiveness is the process of paying attention.

Selective inattention is a term used to describe an aspect of attentiveness in which the subject blocks out those data of consciousness that generate anxiety, guilt, and other unpleasant feelings. It is synonymous with the psychological defense mechanism known as denial. Blunting of attention is an extreme form of inattention in which responses to noxious stimuli are reduced.

Apperception. Apperception, or comprehension,

implies the clear and correct recognition of the meaning of the data of perception. When a mental image is clearly perceived but is falsely interpreted or understood, one speaks of abnormal apperception. This may occur in psychoneurosis in relation to severe anxiety, in psychotic states as a result of delusions, and in organic brain disease with sensory aphasia.

Suggestibility. Suggestibility exists when a patient responds compliantly with unusual readiness. Suggestibility is seen in psychoneurosis, especially in conversion reaction, and plays an important role in hypnosis. In psychosis it can be seen in automatic obedience, echolalia, echopraxia, and cerea flexibilitas. If the patient has a good and trusting relationship with an individual, this increases his suggestibility. Suggestion is the process of influencing a patient to accept uncritically an attitude or idea.

Negative suggestibility, in which the patient does the opposite of what is suggested, is seen normally in children and in catatonic schizophrenia as negativism, which means the perverse resistance to suggestions or advice.

Suggestion plays an important role in communicated insanity (*folie à deux*), a psychotic reaction in which two closely related and associated individuals simultaneously show the same symptoms and one member seems to have influenced the other. It may also affect three members of a family; then it is called *folie à trois*.

Hypnosis. This is an artificially induced disturbance of consciousness that may superficially resemble sleep but is physiologically distinct from it. It is characterized by heightened suggestibility. As a result, a variety of sensory, motor, and memory abnormalities may be induced by the hypnotist.

Hypnoid state. This was hypothesized by Freud to be an alteration of consciousness that occurs characteristically in hysteria during periods of emotional stress. It is characterized by heightened suggestibility and provides a basis for hysterical somatic symptom formation, feelings of depersonalization and derealization, and fugue states.

Startle reaction. This is a reflex response to an unexpected stimulus of great intensity. It is associated with a sudden increase in the level of consciousness and a diffuse motor response involving flexion movements of the trunk and extremities (hence, in German, *Zusammenschrecken* reflex). It occurs in normal individuals. It may be elicited more readily and with a greater motor excursion in acute anxiety neurosis, such as occurs following a traumatic battlefield experience during wartime.

Effects of pharmacological agents. Various pharmacological agents affect the level of consciousness. Most sedative and hypnotic agents act on the central nervous system diffusely. In small amounts, they reduce perceptual acuity and motor skills. In larger amounts, they produce, in succession, somnolence, sleep, stupor, coma, and death.

Reduction of the level of consciousness by means of sedative and hypnotic medication is induced for the relief of mental or physical suffering. Some of the medications of the phenothiazine series act selectively on the central nervous system so as to reduce the affective experience of suffering without simultaneously reducing the over-all level of sensorimotor efficiency.

It has been hypothesized that the phenothiazines and some other psychopharmacological agents selectively diminish the activity within the multisynaptic short circuits of the reticular activating system (RAS), thus leaving the functions of the cerebral cortex essentially unimpaired. This is in contrast to the barbiturates and other sedative medications, which diminish central nervous system activity diffusely, including the cerebral cortex and the long pathways.

Sleep. Sleep is a complex state of altered consciousness consisting of at least four separate stages of varying depth, sensory and motor activity, and responsiveness.

In clinical descriptive terms, sleep has many variants. It may be deep, continuous, and refreshing. It may be light, intermittent, and exhausting. It may seem dreamless or filled with dreams. When dreams appear, they may be good dreams or bad dreams.

There is relative unresponsiveness to stimuli in sleep, the degree of unresponsiveness depending on the stage of sleep, the amount of fatigue, the state of mind of the subject (whether troubled or at ease), the intensity and quality of the stimulus. For example, a mother may sleep deeply, unmindful of loud noises all about her, and yet awaken at once at the first soft cry of her baby. Among the strange expressions of consciousness in sleep is the commonly experienced ability to wake up at a specific time in the morning.

Sleep occupies most of the 24 hours of the day at birth and is interrupted only briefly because of hunger or physical discomfort. The period of sleep gradually shortens until it occupies 7 to 8 hours in the normal adult and becomes still shorter with advancing age. Normal sleep requirements vary widely from as little as 4 hours a night in exceptional instances at one extreme to 10 hours or more at the other.

Insomnia is a pathological inability to sleep. In catatonic or manic excitement, the patient may remain uninterruptedly sleepless for 20 or more hours at a time. These reactions of extreme excitement may terminate with fatal exhaustion, which is at times associated with hyperthermia.

Early morning insomnia is a sleep disturbance occurring characteristically in depressions. In these instances the patient falls asleep readily enough but awakens in a few hours, bathed in anguished perspiration. This sleep pattern is commonly associated with anorexia, weight loss, feelings of sadness, and suicidal ideation.

Inability to fall asleep is a form of insomnia more characteristic of the psychoneuroses. In these instances the patient is often afraid to fall asleep be-

cause of nightmares. Patients with traumatic neuroses induced by battlefield experiences often are afraid to fall asleep because of the severity of their nightmares.

Pavor nocturnus is a type of sleep disturbance encountered in early childhood in which the child is usually found sitting up in bed screaming in terror, in the grip of a nightmare of hallucinatory intensity. In the course of the episode the youngster may seem to be reacting to frightening people or animals and acts as if unaware of the presence of reassuring parents. The episode is brief and self-limited, and the youngster spontaneously drops off to sleep after it. Often the child has no recollection of the episode the next morning. On the other hand, these episodes may become the basis of a fear of falling asleep.

Hypersomnia is often seen in depressive reactions occurring in psychoneurotics. In these instances sleep is a retreat from painful encounters with the real world.

Reversal of sleep habit is a common accompaniment of hypersomnia. In these instances the patient tends to sleep soundly through the early morning hours, wakes up gradually in the early afternoon, and achieves full wakefulness at a time when most people are going to bed.

Drowsiness is a state of consciousness that intervenes normally between sleep and waking and is characterized by a general slowing up of the thought processes, with a tendency to concreteness in thinking, diminished perception, and clumsiness in motor responses.

Somnolence is abnormal drowsiness. It occurs in a variety of toxic, metabolic, and inflammatory disorders of the brain and with brain tumors that press on the floor of the third ventricle.

Epileptic and convulsive disorders. The essence of epilepsy from the standpoint of diagnosis is the periodic appearance of a recurring pattern of short-lived disturbances of consciousness. The convulsive disorders are discussed in detail elsewhere, but it seems appropriate to include a brief review of the epileptic disturbances of consciousness in this section.

Petit mal and **grand mal** seizures are characteristically associated with full loss of consciousness in the midst of the attack. In petit mal, consciousness blinks on and off, as it were, for intervals lasting between 1 and 40 seconds each. These individual attacks are not associated with a preattack warning and are not followed by characteristic subjective or objective sequelae. EEG records in the midst of such attacks invariably reveal a spike and wave pattern having a frequency of approximately three of these complexes per second. The attacks may occur as often as 100 times in a single day or as occasional, isolated attacks days or weeks apart.

The disturbances of consciousness associated with grand mal epilepsy are much more complicated. The actual muscular movements are typically preceded by an **aura**, which in itself may consist of a variety of

clouded states of general awareness, including feelings of unreality and depersonalization. Commonly, these feeling states are not only vividly experienced but often remembered by the patient. Such preconvulsive alterations of consciousness may last for hours or even days before the actual seizure and may give the patient an opportunity to get to a place of safety. During the actual convulsion, loss of consciousness is complete, and amnesia for the events during the actual seizure is also complete. After the grand mal seizure, patients display an obtunded state of consciousness, which varies in duration from a few minutes to a period of hours. During this time, the EEG may show diffuse, symmetrical slow wave activity. Amnesia for the postseizure period may be complete or interspersed with fragmentary islands of recall. This period has been called the postictal twilight state.

Twilight states or dream states of consciousness can occur as independent phenomena apart from grand mal seizures. They are characterized by circumscribed periods of intellectual dulling, disturbance in consciousness, confusion, and disorientation. Brief auditory and visual hallucinatory symptoms and schizophrenic-like psychotic reactions have been described within the complex of the epileptic disorders. Generally, there is an amnesia for actions during this period. Characteristically, all these seizure patterns are associated with electroencephalographic abnormalities, which coincide in duration with the duration of the abnormality in the state of consciousness. Similar dream states are encountered in dissociative reactions, but with normal electroencephalograms.

The reticular activating system acts as an arousing mechanism that increases alertness when stimulated. Sensory stimulation serves a 2-fold function: it brings information from the environment, thus providing specific data concerning reality; and it arouses and alerts the organism through collateral pathways to the RAS.

Corticofugal pathways also send collaterals to the RAS, thereby placing the latter under the control of sensory stimuli from without and cerebral cortical elaboration from within. Stimulation of the RAS facilitates both the general sensory inflow and the lower motor outflow. Inhibition of the RAS inhibits sensory inflow and lower motor outflow. In this way, the RAS can be said to affect both the cognitive and conative aspects of consciousness.

Disturbances of Orientation

Orientation may be defined as the ability to recognize one's surroundings and their temporal and spatial relationships to oneself or to appreciate one's relations to the social environment. The capacity for orientation involves the following categories: (1) **Time:** knowledge of the hour, day of the week, date, month, season, year. (2) **Place:** name of present location, the address, one's home address, the distance between present location and home address, reason for being in this place at this time. Inquiries in this area may reveal pathological denial of physical illness and the existence of other types of delusional systems. (3) **Person:** identity of self and others in the immedi-

ate environment. This includes not only a knowledge of names but also an appreciation of the role of each in that setting.)

The capacity for orientation depends, in the main, on three factors: (1) the availability of perceptual data from the outer world, (2) the availability of the stored data of recent memory, and (3) a commitment to the demands of reality, which is part of the emotional equipment of the mature adult.

One may speak of a specific drive to seek out and maintain accurate orientation as a psychological quality characterizing the mature adult. Normally, the inability to establish one's bearings generates anxiety and appropriate orientation-seeking behavior. A normal person, for example, awakening in strange surroundings after a deep sleep may have a brief period of bewilderment, during which he scans his environment for clues, draws on his stored memory for recent events, and, finally, with a sense of relief, orients himself correctly. If he awakens from a particularly vivid dream characterized by a deep sense of the reality of the events in the dream, he may have a similar brief struggle to reestablish his orientation. If a patient wakes up from a coma, he may not be able to marshal sufficient data to orient himself. He may suffer from anxiety and bewilderment and respond to specific inquiries concerning orientation with panic and requests for information or by admitting that he does not know the answers to the questions.

In a variety of settings, individuals abdicate their firm commitment to reality. Adults in normal recreational settings, for example, deliberately cultivate flight from reality as part of the recreational process. In the theatre, surrender to the make believe of the play may be so complete that it takes a period of active struggle to reestablish contact with the real world when the performance is over. Alcohol and other common central nervous system inhibitory substances encourage, and temporarily make possible, flights from reality and facilitate rapprochement with the world of make believe.

The phenomenon of the imaginary companion may be cited as an example of flight from reality that takes place within the limits of normal. It has been commonly observed that an essentially normal child will create an imaginary companion for himself and will endow this product of his fantasy with qualities of reality. He gives the companion a name, a definite personality, and even an imaginary family. This phenomenon is seen most often when the subject is an only child or is for any reason shut off from real playmates. In general, the imaginary companion is so created by the child that it has everything the child desires but lacks. Thus, at this stage of development the child is able to enter into transient but easily reversible breaks with reality.

Patients with diffuse organic brain disease provide a paradigm for understanding the phenomena of dis-

orientation. For many years the incorrect orientation answers of brain-injured patients were too briefly dismissed with "The patient is confused," or "The patient shows memory impairment." On close observation, orderly patterns can often be discerned within the over-all picture of disorientation. In addition, what is sometimes described as an inability to remember is in actual fact a consistently repeated pattern of *misremembering*.

Disorientation for time. Hospitalized patients without organic brain disease very commonly lose track of the date, the day of the week, and even the month. Thus, correct answers may be expressive of an alert and intact sensorium, but errors in these categories are not diagnostic of organic brain disease. An error in the year, on the other hand, is of diagnostic significance. It is in relation to the year that one commonly encounters a persistent pattern of *misremembering*.

A patient may give the year as 1958, and, even though he is corrected repeatedly, on each subsequent questioning he persists in stating that the year is 1958. Thus he "remembers" quite dependably the wrong year. To characterize this as a simple lapse of memory is to miss the point that the patient is remembering what he *wishes* to remember; that is, he is responding to a wish or to a feeling that he is living in a year that was, perhaps, the last time that he was in good health. The incorrect response, "The year is 1958," expresses a wish to be well rather than a simple failure of memory.

Errors for the time of day are not significant as evidence of organic brain disease unless the error crosses a mealtime. Brain-injured patients commonly show errors for time of day if awakened from a nap, thinking, for example, that lunch or supper is actually breakfast.

A patient cited by Weinstein and Kahn always gave the time of day as 7 P.M., "because that is when my daughter comes to visit me." This patient deliberately avoided contact with a clearly visible wall clock in the process of denying the correct time.

In giving their personal history, many patients condense incidents in time that should actually be separated.

A patient may report the birth of a younger sibling and the occurrence of an operation, such as a tonsillectomy, as taking place the same year when, in fact, the younger sibling was born when the patient was age 3 and the operation took place at age 6. In some such instances, it is possible to demonstrate that guilt over sibling rivalry on the one hand and the childish misinterpretation of an operative procedure as a punitive act on the other, although temporally separated, are condensed as a retrospective temporal falsification so that crime and punishment become fused in memory as a single event (see *paramnesia*).

Neurotic problems involving rebellious attitudes or a need to avoid painful reality may result in patterns of persistent tardiness. The affective state also plays a role in temporal orientation. During moods of elation, time seems to move quickly, whereas depressive moods are associated with a feeling that time is dragging.

Some anxious patients are unable to tolerate free time and have a need to fill all the temporal nooks and crannies of the day with prearranged activities. Such patients often suffer from a fear of loss of impulse control and defend themselves against acting out by overscheduling themselves. On the other hand, some patients, with a fear of their own passivity, will complain that they are too tightly scheduled. The outer controlling elements are experienced as potentially dangerous forces capable of overwhelming the victim. Such patients are incapable of tolerating authority and may present particular problems in relation to school and military service, where punctuality is a *sine qua non* for successful performance.

Disorientation for place. The brain-injured patient in a general hospital may express the wish to be well by insisting that he is not in a hospital but in his home. When one such patient was asked to explain the presence of the doctors and nurses who were all around her, she answered, "These people have taken over my home and have made it over to look like a hospital, but it is really my home." Other patients will give the name of the institution correctly but will characterize it as a hotel, a restaurant, a convalescent home. That is, in various ways they will deny the gravity of the illness by denying that they are in a hospital. On occasion, the patient will give the name of the hospital correctly but will place the hospital close to home, saying, "I live a block away," or "I live across the street," when, in fact, home may be miles away. At times the patient will locate himself in another hospital in which he was treated many years ago for a relatively minor illness from which he recovered. In this spatial dislocation he is expressing a *déjà vu*. He says, in effect, "I've been here before, and I went home in good health." Temporal disorientation commonly accompanies this pattern of spatial disorientation. In duplication or reduplicative *paramnesia* patients will give the name and location of the hospital correctly but insist that another "bad" hospital with the same name is located nearby.

These meaningful alterations, which are so clear in the case of the patient with diffuse brain disease, provide the clue for the disorientations in place encountered without organic brain disease. Schizophrenic patients may be disoriented for place in less predictable ways but always meaningfully in terms of their delusions.

For example, a schizophrenic patient asserted that he was in a prison elaborately disguised to look like a hospital with a staff of jailers disguised as doctors and nurses who were all engaged in a charade to elicit incriminating facts about the patient and his family. He made a severe suicidal attempt because he believed that only upon his death would the jailers spare the lives of his loved ones.

Disorientation for person. A married female patient displaying disorientation for person may give her maiden name and will insist that she is not married. Such denials often express elements of marital disharmony from which the patient wishes to take flight. It may also be associated with temporal disorientation representing regression to a time preceding the onset of illness.

Anosognosic patients may misidentify in a manner to confirm the denial of illness. The doctor in a white coat may be identified as a fish peddler and the place of their encounter the Fulton Fish Market. Some physical or characterological trait in a doctor or nurse may be the basis for a persistent misidentification of this person as a friend from the past who has no connection with illness. The doctor may be identified under such circumstances as a former teacher or an insurance salesman.

The tendency to divide the world into good and bad elements and then to create delusional systems that, in effect, embody this split resulted in a delusion expressed by a woman with one son named William. She claimed she had two sons, one named Bill, who was a good son, and one named Willie, who was bad. This duplication may involve not only the entire person but part of a person. For instance, a hemiplegic patient may insist that he has two left arms, one good left arm and one bad left arm.

Many times, patterns of disorientation in reversible brain disease will persist after the acute brain disease has subsided. Or it may clear up only to recur in a setting of emotional stress.

The concept of self may be so chaotic that the vulnerable individual tends to be highly suggestible and to identify with any dominant person he is with. He may incorporate specific mannerisms of speech and dress and self-destructive patterns of behavior, such as narcotic addiction. This instability of self-concept is particularly conspicuous in teen-aged girls. For this reason, they are vulnerable to mass hysterical behavior, as television audiences know from watching their responses to currently popular public performers. The chaotic concept of self is what Erikson referred to as the identity crisis. Confronted with an essentially insoluble dilemma concerning one's role in life, many teenagers go beyond experimental introjections and identifications and take flight into psychosis.

A teen-aged girl could not decide whether to be a successful writer and civic-spirited citizen like her father or a beautiful narcissistic woman like her mother. The patient had a prominent nose, which caused her to resemble her father. A plastic surgeon modified her nose, achieved an excellent cosmetic result, and succeeded in emphasizing delicate feminine features, which resembled her mother. Post-operatively, she went into an acute schizophrenic state, characterized by delusions that she was a sought after beauty who had a great mission to save the world as a second Florence Nightingale.

Disorientations in all spheres tend to parallel and support each other. Through secondary elaboration, an inner consistency is achieved, like the consistency that often characterizes a dream. There is an expansion and embellishment of certain details to make for this consistency. If the time precedes the onset of the patient's illness, then the place is apt to be consistent with that time. The people are similarly misidentified, and the reason for everyone being together at that time and in that place is rationalized by

complex delusional systems. When the disorientations in the delusional system are logically organized so that they have a "rational" inner consistency, the delusional system has been systematized. Systematized delusions are more resistant to correction and tend to carry a more serious prognosis.

Disturbances of Memory

Memory is based on three essential processes: (1) registration, the ability to establish a record of an experience in the central nervous system; (2) retention, the persistence or permanence of a registered experience; and (3) recall, the ability to arouse and report in consciousness a previously registered experience.

A good memory involves the capacity to register data swiftly and accurately, the capacity to retain these data for long periods of time, and the capacity to recall them promptly in relation to reality-oriented goals.

During the process of registration, there must be a physiologically intact alert central nervous system. There must also be a sufficient number of repetitions of exposure to the data to stabilize the memory trace. An actor who needs many repetitions to memorize a script is called a slow study. At the other extreme are gifted individuals who in a single exposure can master a dramatic script, a musical score, or a school lesson.

Emotions associated with the learning process play a crucial role in determining the permanence of memories. In infancy and early childhood, the entire learning process is tied up with satisfactions based on the relief of biological needs by loving parents. Thus, in early childhood, there is a brain maximally receptive to learning in purely biological terms, there are attentive adults who are prepared to provide the repetitions necessary for learning, and there is a pattern of reward based on the loving responses of the parents as teachers. For all these reasons, it is no accident that the first language learned is called the mother tongue and that the mother tongue is normally the first language that returns on recovery from brain injury in patients who knew more than one language prior to the injury.

Although a good memory is one of the factors in the complex of mental capacities that make up intelligence, phenomenal feats of memory are occasionally encountered in settings of apparent mental retardation. The latter usually involve rote memory, the capacity to retain and reproduce data verbatim, without reference to meaning. In logical memory, on the other hand, problem-solving in relation to a reality-oriented goal is paramount.

In addition to quantitative there are also qualitative differences in memory. Some persons are particularly well endowed with visual memory and can recall images with virtual hallucinatory intensity. Such subjects are called eidetic individuals, and the reproduced memories are called eidetic images. This eidetic capacity tends to occur in childhood and subside with age, so that it is rare after adolescence. Memory for music, mathematics, muscular movements such as those involved in the performing arts, spatial relationships, and emotional feelings may be cited as examples of nonverbal memory. Verbal memories depend on the development of verbal skills.

Disturbances in registration. (Registration depends on the level of consciousness. Anything that diminishes consciousness, such as alcoholism or concussion, interferes with registration.) A prizefighter may go on for several rounds to win a fight after a dazing blow to the head and yet have no recoverable memory for the events following the blow. A circumscribed memory loss of this kind occurring during the time following an acute brain injury is called anterograde amnesia. An alcoholic may behave in a socially acceptable manner for an entire evening and yet have no recoverable memory for the events of that evening. Disturbed states of consciousness lasting for weeks and months associated with encephalitis, subarachnoid hemorrhage, and severe brain trauma may be followed by a permanent inability to recall the events experienced during that period. In all of these instances, the subsequent defect in recall starts with primary defects involving registration and retention.

There are conditions in which registration seems to be impaired because the patient appears to be totally nonreactive. This occurs in catatonic schizophrenia and in severe panic states. However, when the brain is intact from an organic point of view but perceived experiences are repressed or denied for purely emotional reasons, registration is normal. In these instances, seemingly nonobserved events can be recalled subsequently, either directly or with the use of specific techniques for eliciting forgotten or repressed memories, such as hypnosis or narcoanalysis.

Disturbances in retention. In the establishment of lasting memories, there is a preliminary learning stage during which the memory trace is unstable. The memory curve or the curve of forgetting is a graphic representation of the relative amounts of memorized material that can be recalled after various intervals of time. For individuals with good memories, the memory traces are quickly established, and the curve of forgetting is prolonged and may extend over the entire lifetime of the individual. In some instances of organic brain disease, the curve of forgetting is accelerated. (In Korsakoff psychosis, memory for recently acquired facts may decay in a matter of seconds, without any residual capacity for recall.)

Retention is a property of nerve tissues in general. Nerve cells and their processes may be compared to tape recorders that retain at least a partial record of the impulses that have passed along them. There is an enormous capacity for units of information and for specificity of records of this kind in the brain.

It has been hypothesized that the registration stage of memory depends on the formation of ribonucleic acid (RNA) within the nerve cells and their processes and that specific memories derive their individuality from specific modifications in the RNA molecule. According to this hypothesis, each such RNA molecule is the storage device for the memory system and, at the same time, a template or stencil that can run off duplicates of the molecule as part of the mechanism of recall.

It has also been hypothesized that in the aging brain the basic supply of RNA is diminished and that this is the specific organic deficit underlying the proverbial weakness of memory in the aged. Indeed, it has been suggested that additional

RNA, parenterally supplied, can reverse the memory defects of senility.

Disturbances in recall. Recall is, in the long run, the most important aspect of memory, since it is only in the examination of the process of recall that we acquire evidence that memory is intact or impaired.

Amnesia. Amnesia is the partial or total inability to recall past experiences. The events of infancy and early childhood up to the 5th year are commonly forgotten as part of the normal childhood amnesia.

According to psychoanalytic theory, an important basis for childhood amnesia is the need to control and repress various infantile wishes that are forbidden by parents. As infantile fears of punishment are relieved during psychoanalysis, many of the events of childhood amnesia are increasingly subject to voluntary recall.

(From a theoretical point of view, a relatively sharp distinction can be made between the amnesias based on organic brain disease and those disturbances of purely emotional origin. The latter fulfill specific emotional needs and tend to subside when these are no longer operative. The amnesias of organic brain disease involve disturbances in registration and retention and are essentially nonrecoverable. Most often they affect the recall of recent events and leave the memory for remote events relatively intact. This is described as retrograde amnesia. Thus, in retrograde amnesia, there is amnesia for a period prior to a traumatic event. Such an amnesia may be psychological as well as organic in origin. If the brain disease is organic and progressive, impairment in recall worsens. The amnesias of emotional origin either improve with treatment or remain stationary,

The sharp distinction between amnesias of organic and emotional origins is made for purposes of description and clarification. Most amnesias seen in relation to organic brain disease are, in fact, mixed amnesias in which organic deficits and emotional interference with recall both play a role.

Hysterical amnesia is a loss of memory for a particular period of past life or for certain situations associated with great fear, rage, or shameful humiliation. This form of amnesia is highly selective and systematized to fulfill the patient's specific emotional needs (see hysterical fugue state).

The rule of Pitres states that, in a person who knew more than one language prior to a brain insult, the first language that returns is the mother tongue.

E. E. Krapf cites a case of polyglot aphasia that illustrates the negative role emotion can play during the period of recovery. A brain-injured young man grew up in a Spanish-speaking country, but his mother tongue was English. In this case the mother-child relationship was a highly disturbed one, and the patient grew up with the image of his mother as a menacing figure. As memory for language returned in this brain-injured boy, he clearly preferred Spanish. Reduction in comprehension of English was especially noticeable during his mother's visits.

Halpern cites another case of polyglot aphasia. In this case, on recovery from a severe head injury, a Hebrew-speaking man whose mother tongue was English followed the rule of Pitres and used English first. However, on return from the hospital

to his Hebrew-speaking wife and children, he went into a severe depression when he found he could not communicate with them. During the following days, his mastery of Hebrew returned, and thereafter his fluency in Hebrew returned more rapidly than his recovery of English.

The brain-injured patient who is highly motivated may succeed in overcoming organically determined impairments of recall by a variety of mnemonic devices. For example, in response to a request to name an abstract word or concept, he may start with a concrete visual image that is charged with highly personal significance. In his search for the correct word he may then go on to make writing movements with his head. Finally, after much effort exerted over this tortuous path, he arrives at the abstract word for which he is searching. Thus, in order to discover subtle memory defects in brain-injured patients, it is necessary to inquire into the mechanism of remembering as well as the actual content of what is remembered.

In contrast to the aphasic impairments of recall, which are highly circumscribed and involve specific words or actions, is the impairment of recall associated with the hysterical fugue state (dissociative reaction). This is a form of amnesia that sets in following a severe emotional trauma. A terrifying experience on the battlefield or a momentary loss of impulse control that nearly leads to the murder of a loved one may be followed by a complete loss of memory concerning all personal identifying data. Following the precipitating psychological trauma, the patient enters into a period of actual physical flight, which takes place in a state of panic. When the victim comes to, he finds himself far removed from his accustomed habitat and unable to identify his surroundings, his reason for being there, or anything about his past. This form of amnesia is associated with a flattening of affect characteristic of hysteria. Usually, the lost memory is readily recoverable with hypnosis, narcoanalysis, or strong suggestion, particularly when offered in a setting that promises extended relief or actual physical separation from the traumatic life situation.

The dramatic extremes embodied in hysterical fugue states provide the model for more circumscribed example of functional forgetting. Many psychologically traumatic experiences in early childhood are forgotten. What Freud referred to as *repression* in relation to these early childhood traumata is indistinguishable from forgetting in general. Such circumscribed amnesias may be the basis for a chronic state of psychological stress. According to psychoanalytic theory, these forgotten traumata threaten constantly to erupt into consciousness.

Symptom formation, to some degree, has its origin in the ongoing need to keep these memories out of consciousness or to distort and disguise them if they do return. In a sense, the neurotic patient can be said to suffer from memories he is forgetting with only partial success, and in this way the psychopathology of memory is related to the psychopathology of the emotions.

Since nothing registered in the intact brain is ever really lost, in the functional diseases only the capacity for recall is

impaired. In psychoanalytically oriented psychotherapy, the recall of forgotten traumata is facilitated by a systematic attack on the defenses.

Paramnesia. Paramnesia is a distortion of recall usually associated with the inclusion of false details or wrong temporal relationships.

Distortions in recall are encountered in normal individuals. The witness's errors in the courtroom are examples of this. There is in everyone a readiness to distort recall whenever accurate recall impinges on some painful reality. The presence of diffuse organic brain disease has the effect of facilitating and fixating this universally present tendency toward paramnesia.

Fausse reconnaissance, or false recognition, is the feeling of certainty that one is recalling accurately something that is patently inaccurate.

In retrospective falsification, a type of paramnesia sometimes called illusions of memory, false details, meanings, and recollections of a real memory are created in response to emotional needs. A patient may recall a true past event but distort it in accordance with a present need to support a symptom.

In confabulation, there is an unconscious filling in of gaps in memory by imagined experiences that the patient believes, although they have no basis in fact. These recollections change from moment to moment and are easily induced by suggestion. This phenomenon is most characteristic in Korsakoff psychosis.

Pseudoreminiscence incorporates both confabulation and retrospective falsification.

Déjà vu is an illusion of recognition in which a new situation is incorrectly regarded as a repetition of a previous memory. It can occur in normal individuals, particularly in settings generating anxiety. It is more common in psychoneurotic states and occurs occasionally in the aura of an epileptic seizure. In *jamais vu* there is a false feeling of unfamiliarity with a real situation that one has experienced.

Related to *déjà vu* are *déjà entendu*, in which a comment never heard before is incorrectly regarded as a repetition of a previous conversation, and *déjà pensé*, in which a thought never entertained before is incorrectly regarded as a repetition of a previous thought.

Although the causes of these related phenomena are not known, psychoanalytic evidence suggests that they share with screen memories and day-dreaming the function of psychological defense. Implicit in the feeling "I have experienced this before" is the reassuring further thought "and I have survived in spite of my fears." In short, *déjà vu* is a device to control the intensity of anticipatory anxiety.

The familiar type of nightmare known as the examination dream seems to serve the same function as *déjà vu*. Such dreams occur typically before a school examination or some other life trial. In the dream, the subject is asked to answer examination questions concerning a subject he never studied. In spite of the manifest anxiety in such dreams, the content typically deals with a test that was successfully passed some time ago. As such, it serves to reassure the dreamer that he will pass this test as well.

Hypermnnesia. Hypermnnesia is an exaggerated degree of retention and recall. It can be elicited at times in a hypnotic trance. It is seen in certain prodigies, obsessive-compulsive neurosis, paranoia, and mania.

A screen memory consists of fragments of childhood recollection that break through the barrier of childhood amnesia. The screen memory is often striking for the minutiae recalled. Commonly, there are recollections of bright light. Characteristic also of the screen memory is its tendency to return to consciousness repeatedly in an obsessive fashion.

Paradoxically, the qualities of exaggerated accuracy and feelings of certainty that accompany these hypermnnesias are deceptive. There are temporal and spatial alterations and an emphasis on trivia that combine to ward off from conscious recall specific traumatic memories of childhood. Thus, these memories may be more accurately classified among the paramnesias.

Disturbances in Perception

Perception is the awareness of objects, qualities, or relations that follows stimulation of peripheral sense organs, as distinct from the awareness that results from memory. (Thus, perception is the necessary precursor of memory and is connected with memory via the process of memory registration.)

There are as many categories of perceived data as there are types of end organs. The latter include auditory, olfactory, gustatory, tactile, and kinesthetic.

Perception also includes discrimination, that is, the capacity to perceive the differences between two or more objects in respect to certain characteristics. Depth perception is the capacity to perceive the distance of a given object or objects from the observer or the relative distance from front to back in the perception of solid objects.

Agnosia is an inability to recognize and interpret the significance of sensory impressions because of organic brain disease.

Perception may be the result of relatively simple, affectively neutral stimuli, presented one at a time or two at a time (double simultaneous stimulation or DSS). Stimuli may be complex, involving both visual and kinesthetic factors in making a discriminatory judgment, as in binocular vision; or stimuli may be a combination of visual, olfactory, and gustatory in an essentially gustatory perception.

A disturbance of perception associated with organic brain disease forms the basis for the face-hand test (Bender). If a normal alert adult with eyes closed is touched on his face and hand simultaneously, he recognizes both touches accurately and promptly. In settings of diffuse organic brain disease, including cerebral arteriosclerosis, the subject reports the face touch accurately but does not report the hand touch at all or displaces it up toward the face and locates it inaccurately. Persistent errors on double simultaneous stimulation provide presumptive evidence of organic brain disease. This test is normally positive in children up to the age of 4 or 5. It then

becomes negative until age 60, after which it tends to become positive again. In the intervening age groups, the test provides a useful presumptive sign. In elderly patients who are depressed and who give a positive response, the test tends to become negative as the depression lifts. In all instances of a positive response, further neurological studies are required to demonstrate absolutely that organic brain disease is indeed present.

Between the presentation of a stimulus and its recognition by the observer there is a time lapse called the perception time. This involves time for the transmission of the nerve impulse from the sensory receptor to the appropriate brain centers. More significant is the time involved to overcome an emotionally determined barrier to perception, which exists to protect the individual against traumatic stimuli.

Traumatic stimuli of all categories are modified adaptively by the barrier against stimuli. Alterations in the level of consciousness provide one example, with complete loss of consciousness (fainting) as an extreme example.

Whereas emotionally induced fainting eliminates all perception, circumscribed eliminations of perception may occur as a device for coping with traumatic stimuli. In negative hallucination, an individual with a physiologically intact nervous system fails to perceive a stimulus. It can be induced through hypnosis. When the nonperceived stimulus is excluded from conscious awareness because it is traumatic, it is usually part of the syndrome of hysteria.

Any modality of perception may be disordered in hysteria. Total anesthesia can occur, but diminution in sensation is more common. These perceptual disturbances do not follow recognizable neuroanatomical distributions but involve rather a part of a limb (glove and stocking distribution), half the body, and the mucous membranes (vagina, rectum, nose, mouth, and pharynx). Peculiar to the hysterical anesthetics is the usual involvement of all forms of sensation, superficial and deep, without the dissociation that so frequently occurs in organic sensory disturbances. If the sensory loss is limited to half the body, it is found to stop exactly at the midline, a condition contrary to the normal cutaneous overlapping. Similarly, psychogenic loss of sensation is attested to by the hysteric's perception of the tuning fork on only one side of the sternum or on only one side of the head, an obvious impossibility in view of the normal bone conduction of vibrations.

Repeated testing of visual fields in hysteria may result in a spiral contraction of the visual field. Hysterical blindness may occur.

Macropsia is a condition characteristic of hysteria in which objects appear larger than they really are. They may assume terrifying proportions.

Micropsia is a condition in which objects appear smaller than they really are. It may alternate with macropsia in hysteria, but it has also been described as an aura in some cases of epilepsy.

Hysterical patterns of perceptual disturbance do

not by any means rule out organic disease. These perceptual disturbances often seem to emerge in response to repeated sensory testing. This is not at all the result of a conscious intent to deceive the examiner but is often a naive appeal for help.

Brain-injured patients with left hemiplegia, hemianesthesia, and hemianopsia often steadfastly neglect the entire left side of the visual field. For example, they will eat all the food on the right side of the hospital tray right up to the midline; they will write only on the right half of the page; they will read only the right half of an individual word. In drawing the human figure, they draw only the mirrored representation of the right half of the body, neglecting entirely to draw the left half. In all these instances, there seems to be a selective inattention to the sick side, which manifests itself as an essentially hysterical disturbance in vision. The relationship of the latter to denial of illness seems quite clear: "The sick side does not exist."

Patients with organic hearing impairments have selectively more difficulty hearing emotionally disturbing auditory stimuli. In a sense, these patients with mixed (organic and functional) hearing disturbances are expressing in a selective and more circumscribed fashion the same phenomenon that is encountered in complete hysterical deafness without organic hearing impairment, namely, a blocking out of potentially traumatic auditory percepts.

Hysterical anesthesia has been described as a kind of localized fainting. Frigidity, including all degrees of anesthesia of the vagina and external genitalia, is a common hysterical defense against sexual excitement. In each circumstance, there is a withdrawal of attention from potentially traumatic external events.

Just as withdrawal of attention from a body part can reduce perception to the point of complete anesthesia, so can a sensory end organ be over invested with attention because of anxiety. In the latter instance, there may be areas of hyperalgesia to touch, headaches, and other body pains. In spite of verbal expression of great suffering, the hysterical patient may show a characteristic attitude of unconcern. Complaints of pain may be associated with rigidity of muscles and occasionally bizarre flexion deformities of the extremities and spine. Although the physical complaints typically do not conform to recognizable clinical syndromes, actual physical disease, past or present, may set the stage for use of a specific body part in symptom formation that is without organic basis. This return to a previous symptom or the perpetuation and intensification of a present organic symptom is termed somatic compliance.

In all the perceptual disturbances of hysteria it is not enough to demonstrate that the pattern of sensory abnormality is impossible from the point of view of known neuroanatomical facts. One must also search out the emotional meaning of the perceptual disturbance in adaptational terms, recalling that anesthesia, hyperesthesia, or paralysis commonly serve to defend the patient against sexual or violent impulses that he fears may get out of control.

Hypochondriasis. A generalized withdrawal of

attention from external objects is followed almost always by an increase in the attention focused on the self as an object. If this retreat from the world of real objects is complete enough, a pathological awareness of body feelings emerges, which is the basis for hypochondriasis.

Hypochondriasis is the unshakable belief that physical disease is present, in the face of all evidence to the contrary. As a symptom, it occurs in many forms of mental illness. It is most common in the depressions, particularly those of the involutional period. It may take extreme and bizarre forms in schizophrenia, in which case one may speak more appropriately of somatic delusions. (For example, "My insides are rotting," or "My intestines are filled with vermin or a solid plug of wax.") It may occur in a chronic low grade form over a period of years as part of a psychoneurotic reaction. Abnormal body feelings associated with hysteria tend to be localized and serve to protect the individual against the still longed for but potentially traumatic encounters with circumscribed portions of the outer world. Abnormal body feelings associated with hypochondriasis, on the other hand, tend to be generalized, in the sense that the entire body is involved, and result from a relatively complete withdrawal from external objects. Thus, an important difference between the hysterical and the hypochondriac is the degree to which the real objects in the external world have been retained or surrendered.

Illusions. In an illusion there is perceptual misinterpretation of a real external sensory experience. In a state of anxiety and loneliness, a traveler is apt to mistake a tree trunk for a menacing adversary or a mist for a terrifying apparition. This does not necessarily imply psychopathology. However, a schizophrenic patient may hear an insulting remark in the chime of a clock or feel the sinister hand of death in a casual handshake. This kind of misinterpretation is also known as an illusion. Illusions frequently occur in confused toxic conditions.

Hallucinations. A hallucination is the apparent perception of an external object when no corresponding real object exists. That is, an internal psychological event is mistakenly attributed to an external source. A dream is a simple example of a hallucination in normal experience.

Any modality of perception may be involved in a hallucination. Within the framework of normal hallucinatory experience, hypnagogic and hypnopompic hallucinations should be mentioned. Hypnagogic hallucinations occur in the drowsy state preceding deep sleep. They may contain both auditory and visual elements with great clarity and intensity. At times they are associated with paresthesias in the mouth and hand, the sound of murmured voices, and vague visual images of large objects approaching and receding. The latter group of hypnagogic hallucinations has been called the Isakower phenomenon and

seems to represent a reawakening of the memory of early nursing experiences.

Although it is said that hypnagogic hallucinations occur most often in individuals suffering from hysteria, they can also occur in normal individuals, particularly during childhood and early adolescence. (What has been said of hypnagogic hallucinations is also true of hypnopompic hallucinations, except that the latter occur during the drowsy state following deep sleep and preceding awakening.)

When the schizophrenic patient is wide awake by all neurophysiological criteria, he may experience hallucinations as vivid as those experienced by normal people during dreams. He very often acts on these inner perceptions, as though they were more compelling than the external realities that compete for his attention. He may incorporate illusions into his hallucinations, so that the latter occur alongside of external perceptions and even intermingle with them.

The affective content of the schizophrenic hallucination is more like that of a nightmare. In the acute schizophrenic reactions, unpleasant (dysphoric) elements tend to prevail. This is probably a result of the fact that some unendurable reality being warded off in the psychotic state constantly threatens to break through and contradict the schizophrenic distortion of reality. Auditory hallucinations tend to predominate in schizophrenia as contrasted with the predominance of the visual sphere in the dream.

Hallucinosis is a term for psychotic states in which the patient is well oriented, in spite of the fact that he is hallucinating. Such patients slip in and out of the hallucinatory state, with intervals of insight and lucidity. (Hence, Hughling Jackson's term mental diplopia.)

There is a group of hallucinogenic psychotomimetic drugs that characteristically elicit hallucinosis, that is, hallucinations in a setting of relatively clear consciousness. Mescaline and lysergic acid diethylamide (LSD) are well known representatives of this group. The relative alertness of the subject makes it possible for him to communicate his hallucinations in considerable detail in an experimental situation.)

Under mescaline, visual hallucinations, combined with visual illusions, are most frequently reported. These visual phenomena are vivid and change rapidly. Auditory hallucinations also occur, but less frequently.

Proprioceptive, cutaneous, and hypochondriacal sensations are also reported under the influence of LSD. Visual hallucinations tend to be much less frequent with LSD. In describing their reactions to hallucinatory drugs, particularly to LSD, patients have described compound hallucinations such as "color-hearing" or "sound-seeing." These occurrences have been termed synesthesias.

The relationship of drug-induced hallucinosis to schizophrenia and the value of these hallucinatory states as adjuvants to psychotherapy have been studied extensively, with only equivocal results.

In the convulsive disorders, relatively unformed percepts may occur during the aura. Olfactory and gustatory hallucinations occur in temporal lobe lesions in the so-called uncinat fits. Characteristically, the patient is unable to describe these sensations clearly except to say that they are unpleasant. Other patients may experience nausea or flashes of light as part of the aura. Less commonly, the aura in uncinat fits is associated with complex hallucinatory experiences involving visual and auditory components and possessing an affective quality of reminiscence (for example, *déjà vu*). The nature of the preseizures sensory disturbance often provides important clues for the localization of seizure foci amenable to surgical removal.

Generalized organic brain disease of almost any etiology can be associated with hallucinatory states that are at times indistinguishable from schizophrenia. These reactions may be expressive of drug sensitivities. Atropine and its derivatives may cause characteristic Lilliputian hallucinations in drug-sensitive adults receiving relatively small quantities in the form of eyedrops or in children being treated for enuresis. In Lilliputian hallucinations the hallucinated objects, usually people, appear greatly reduced in size. Although they occur most characteristically in psychotic reactions to a variety of drugs and toxic-metabolic states, they can on occasion occur in psychotic reactions without organic brain disease. They are to be differentiated from micropsia, in which real objects in the environment appear reduced in size.

Similarly, relatively small doses of alcohol or marihuana can produce hallucinations in sensitive subjects. Even the phenothiazines, which are administered to decrease psychotic manifestations, may in specific sensitive subjects intensify hallucinations or elicit new ones.

Patients who are chronically habituated to any sedative substance (alcohol, barbiturates, meprobamate, diazepam, etc.) often experience hallucinations when these drugs are withdrawn (withdrawal reaction). These hallucinatory states are commonly associated with great terror.

A large range of toxic metabolic stressors can elicit hallucinations as part of their action on the brain, for example: uremia, hypoglycemia, diabetic acidosis, alkalosis, hyperparathyroidism, and heart failure. The relief of heart failure with digitalis will at times interrupt a hallucinatory psychosis. On the other hand, a sensitivity reaction to digitalis may start one.

Brain tumors, subarachnoid hemorrhage, uremia, strokes, a broad range of endocrine abnormalities, and a variety of drugs may all play a role in initiating hallucinatory psychosis. The main point is that different chemical agents can produce the same hallucinatory effect in a given individual, and, conversely, a given chemical can produce widely vary-

ing responses among different individuals (Kluever: equivalence of heterogeneous stimuli).

In a hallucinatory state the following elements are to be taken into account:

1. *Projection to the outer world.* At times, hallucinations are perceived with great intensity; at other times, they are perceived as barely audible whispers or barely visible shadows. At times, the hallucination is clearly placed in the outer world; at other times, it is experienced within the body: a picture or a voice located in the head, the chest, or some other part of the body. The images and words may be distinct or blurred. They shade off from unmistakable sensory experiences at one extreme, through vivid imaginations and inspired thoughts, to ordinary thoughts and ideas at the other extreme.

2. *The sensory modality.* For example, a haptic hallucination is one associated with the sensation of touch. Although it may occur in schizophrenia, it is probably more common in delirium tremens, in which these cutaneous hallucinations are commonly associated with visual hallucinations of tiny, crawling animals. Creepy sensations under the skin are known as *formication*, for example, the "cocaine bug." Hallucinations of bad tastes and odors may be encountered as part of the aura of temporal lobe epilepsy (uncinate fit). The latter may also occur in schizophrenia, with complex delusional elaboration. The visual sphere is primarily involved in the hallucinatory phenomena seen in the toxic-metabolic disorders. Anton's syndrome is delusional denial of blindness, associated with hemiplegia of the nondominant side. The auditory sphere is probably the most frequently involved sensory modality in the hallucinations of schizophrenia. Reflex hallucinations may occur in one sensory sphere as the result of irritation in another; for example, a toothache may stimulate an auditory hallucination. Kinesthetic hallucinations may occur in amputees, as the phantom limb experience.

3. *The circumstances that have elicited the hallucinations.* A careful history with physical and laboratory examinations must be carried out to diagnose psychoses with acute or chronic brain disease that might otherwise be indistinguishable from schizophrenia. In all cases involving organic brain disease, reactions of delirium are more apt to occur at night. The sensory deprivation, the loneliness, and the anxiety, which tend to be greater at night, may combine to reactivate a psychotic process that has become quiescent by day. Therefore, careful nursing and security precautions throughout the night are particularly important in the treatment of these cases.

4. *Insight.* The degree to which the patient is aware of the pathological nature of his perceptual disturbances may have both diagnostic and prognostic significance. The element of insight is more likely to be present in the early stages of any psychosis and during the period of recovery. In either case, its pres-

ence tends to be associated with a good prognosis, and such patients are naturally more cooperative for treatment.

5. *The emotional and ideational content of the hallucinations.* The acute reactions of withdrawal from drugs and the toxic deliria are associated typically with great terror. Reactions of flight are common, and such patients, if unattended, may leap out of a hospital window to escape the unspeakable horrors of their psychotic world.

During psychotic states of ecstasy and elation, hallucinatory experiences may involve sexual excitement and feelings of being infused with impregnating rays which result in conception. In paranoid states, voices may be threatening. Rays may cause diseases, poisonings, or strange feelings. Voices may order the patient to commit acts of violence to save himself or the world from unspeakable sin. In depressive states, voices may be derisive and humiliating. They may accuse him of sexual perversion and order him to commit some expiatory act of self-mutilation or self-destruction.

As in dreams, memory traces constitute the building blocks of hallucinations. The past history of each patient provides the clue for understanding their content. The content reflects the effort to master anxiety and to fulfill various wishes and needs. Whereas patients with organic brain disease tend to express simple ideas relating to the wish to be well and to be home, patients with functional psychoses express more complex ideas based on interactions with internalized objects and concern themselves primarily with sexual and aggressive drives that the individual has been unable to master in real life.

Disturbances in Affect

Affect is the feeling tone, pleasurable or unpleasurable, that accompanies an idea. Affect and emotion are used interchangeably and include such feelings as *rage*, *grief*, and *joy*. It determines the general attitude, whether of rejection, acceptance, flight, fight, or indifference. Thus, the affects provide the motivational drive (or psychodynamic) component in relation to every life situation and play a determining role in the thoughts and actions of an individual in health and disease. When an affective state is sustained for a considerable period, we speak of a mood. Affect may be described as shallow or inadequate (emotional flatness), inappropriate (when the emotion does not correlate with the stimulus), or labile (changeable).

Attitude refers to the affective state with which a person habitually confronts his environment. Attitude is determined in early childhood by what Erikson called basic trust.

In the normal developmental sequence, an individual develops a capacity to relate to parents and to later parent figures in school and at work with an attitude of love and basic trust. In settings of family disorganization and in the absence of dependable sources of love and safety, the individual grows up with an attitude of basic distrust.

Where the individual's attitude is one of basic dis-

trust, he tends to be rigidly hostile, suspicious, cynical, and pessimistic toward everyone, even when others attempt to relate to him in a positive way.

Disposition refers to the affective state with which an individual habitually confronts himself. Whenever what Erikson called basic security has evolved, there is also a clear sense of personal identity. Associated with this is a sense of well-being and optimism, which tides the individual over the inevitable recurrent life crises that generate anxiety and depression in everyone.

Anxiety. Anxiety may be defined as a disagreeable emotional state in which there are feelings of impending danger, characterized by uneasiness, tension, or apprehension. The cause is usually unconscious or unrecognized intrapsychic conflict. Anxiety is associated with a characteristic pattern of autonomic nervous system discharge involving altered rhythm of respiration, increased heart rate, pallor, dryness of the mouth, increased sweating, and musculoskeletal disturbance involving trembling and feelings of weakness.

Anxiety is to be differentiated from fear, in which the foregoing combination of feelings and nervous discharges occur as a reaction to a real conscious and external danger that is present or that threatens to materialize.

Tension should also be differentiated from anxiety. In tension, the patient feels tight psychologically as well as physically. Tension is associated with conflict as a component of anxiety.

Panic is a state of extreme, acute, intense anxiety, accompanied by disorganization of personality and function.

In infancy, anxiety is hypothesized to be a diffuse, objectless feeling of dread stemming from the discomforts of unsatisfied needs. As the infant comes to identify the people in the environment who satisfy his needs, anxiety appears as a response to separation from them. With biological development, he is able to make complex behavioral responses calculated to prevent separation or to take action to bring separation to an end. As part of the child's anxiety reaction, he develops physical maneuvers to protect the body, to fight off the attentions of unwelcome individuals, or to take flight. Anxiety at this point involves not only a feeling of dread and the concept of danger but also a positive relationship to a specific individual (usually the mother) capable of relieving the danger. As a consequence of this relationship, the anxiety reaction becomes mingled with a feeling of hope.

As the child develops, he learns to anticipate the danger of separation and to initiate maneuvers to avoid it before it starts. As this is accomplished with increasing success, the gross reaction of discomfort subsides, and in time anxiety is reduced to a mere signal of danger, which sets off appropriate responses so swiftly and silently that there is no conscious awareness of danger in the entire process.

When confronted with an unprecedented danger or when the previous solutions are no longer available, the silent signal of danger once again becomes a conscious clamor, and once again there are psychologically meaningful actions representing calls for help and preparations for fight or flight. If a solution is still not forthcoming, anxiety increases progressively. At one point, expressions of helplessness and hopelessness ensue, with panic and various pathological forms of withdrawal from the traumatic environment.

As the infant develops strength and understanding, he becomes increasingly capable of accepting periods of separation from his mother and increasingly capable of accepting suitable substitutes for her during periods of enforced separation.

Realistic dangers continue throughout life. Such stressful situations still call forth the feeling of dread, the impulse to fight or take flight, and all the associated physiological concomitants. Commonly, the stressor is readily identifiable—for example, an impending operation. At other times the source of anxiety is more difficult to identify. In the early stages of organic disease, a reaction of anxiety to the vaguely sensed organic impairment may be the earliest clinical symptom preceding the appearance of any other localizing somatic symptoms.

Whenever the psychological adaptational mechanisms threaten to decompensate, anxiety appears. This may occur in a chronic low grade form as a constant accompaniment to life. This occurs when a more or less compensated mental disorder exists. Sudden changes in the life situation may evoke an increase of anxiety or precipitate an episode of panic as a warning that more disastrous emotional decompensation is in the offing. Thus, the presence of generalized anxiety or the occurrence of anxiety attacks are indicative not of any one clinical entity but are rather psychophysiological signals of danger that can occur in any diagnostic category of physical or emotional disease.

Free-floating anxiety is the nucleus and key symptom of neurosis. It consists of a feeling of dread that the patient cannot logically assign to a specific cause. In the quest for causality, patients suffering from free-floating anxiety are always ready to attach it to some suitable ideational content.

Anxiety reaction is a psychoneurotic state based primarily on free-floating anxiety. It is characterized by irritability, anxious expectation, pangs of conscience, and episodes of panic. There is a hypersensitivity to ordinary sights and sounds, as a result of which startle reactions occur frequently and with minimal sensory provocation. Cardiac palpitation, breathlessness, giddiness, nausea, dryness of mouth, diarrhea, compulsive eating, urinary frequency, seminal emissions, blurring of vision, general physical weakness, and other physical manifestations may occur chronically as part of anxiety neurosis. In an effort to reduce the unpleasant feelings associated with anxiety, the individual evolves a variety of defensive devices that in their entirety constitute many of the clinical manifestations of psychiatric disorder.

Conversion hysteria, for example, is a well known pathological device for reducing or eliminating free-floating anxiety. It is a psychoneurotic reaction characterized by sensory and motor deficits without a corresponding structural organic lesion. The effect of a hysterical paraplegia, for example, may be to prevent access to a situation feared by the patient because of unconsciously desired and rejected erotic or aggressive impulses. Often the physical symptom is so effective in alleviating the anxiety that the patient displays an attitude of calm (*la belle indifférence*) that contrasts strangely with the extent of the physical disability. *La belle indifférence* is an example of inappropriate affect.

Anxiety hysteria is a psychoneurotic reaction in

which the patient develops specific fears or phobias in relation to situations that might stimulate erotic or aggressive impulses unconsciously desired and rejected by the patient. A similar anxiety-relieving role can be made out for many of the symptoms of the obsessive-compulsive reaction and schizophrenic reaction.

Patients rarely employ a single fixed pattern for relieving anxiety. They try one and then another, and when these reactions fail, they may try still a third. This is repeated until the best adaptation possible under the circumstances is attained. And then, if the circumstances change, the pattern of adaptation may change again. In time, one pattern of adaptation does tend to become fixed in most patients.

In all instances, however, the clinical picture is best understood in adaptational terms in which a dangerous impulse is permitted some modicum of indirect or disguised discharge and the need for restraint and punishment is also permitted some degree of gratification, albeit in disguised form. These conflictual strivings are synthesized and harmonized in a way to reduce the amount of suffering caused by anxiety, and together they form the clinical symptom or reaction.

For example, a young woman was brought into the emergency room of a general hospital by her sister and brother-in-law with an adductor spasm of both lower extremities and an inability to walk. This motor abnormality was without accompanying organic disease. The emergency room physician gave her a small quantity of Amobarbital sodium intravenously, with the strong suggestion that her leg muscles would relax and return to normal when he finished counting to 10. At the appropriate signal, the patient relaxed, got off the table, and walked out of the emergency room, apparently elated. Four hours later, she was returned to the emergency room in a catatonic stupor, for which she had to be hospitalized. At that point, information was elicited for the first time that the patient had just recently moved into her sister's household and had suffered from guilt and anxiety as a result of illicit sexual play with her brother-in-law. Thus, removal of the hysterical defense (adductor spasm) caused this patient to regress to a psychotic defense (catatonia).

Depression. Depression, or a feeling of sadness, shares with anxiety a preeminent place among the most frequently expressed human complaints. Depression may vary in intensity from mild dejection to feelings of deep melancholia and profound despair. Just as fear, as contrasted with anxiety, is a reaction to real danger, so grief, contrasted with depression, is a reaction to a real loss.

The reaction of grief or mourning, which is the appropriate emotional response to a real loss, can be encompassed within the limits of normal reaction patterns. At the outset, grief may be expressed by uncontrollable crying or a shocklike state, with confusion, temporary panic, and thoughts of self-destruction. There may be physical weakness and loss of appetite, withdrawal of attention from the surrounding world, and inconsolability. After the initial period of mourning, there is a restoration of interest in the world. However, each new reminder of the loss reawakens the reaction of grief. The associated affective changes may go on for months and constitute what Freud called the work of mourning. This reaction may be accompanied by irritability and feeling of guilt. In time, the bereaved accepts the irrevoca-

bility of the loss, works through the complex issues raised by his sense of guilt, and is restored to normal.

Where the emotional development of the bereaved is inadequate and where feelings of guilt are very great, the mourning reaction may go on more or less indefinitely and merge into a pathological state of reactive depression. Thus, reactive depression may be defined as a psychoneurotic reaction characterized primarily by feelings of sadness, pessimism, lassitude, and inadequacy. It is commonly associated with anxiety and is precipitated by some loss. The actual loss may involve a loved person, physical health, beauty, or social position.

Anaclitic depression refers to the syndrome shown by infants during the first years of life if deprived of the attentions of a suitable mothering figure. Anaclitic means "leaning on" and is a psychoanalytic term denoting an infant's dependency on his mother for his sense of well-being. On separation from the mother, the infant goes through a characteristic sequence of changes. There is an initial phase of protest, characterized by intense crying and struggling. If this state of affect deprivation continues, the infant lapses into the phase of despair. At this point behavior suggests hopelessness. Struggling decreases, and crying is softer and monotonous. In children's hospitals this quieter state is commonly misinterpreted as a state of diminished distress. Actually, it is a state of mourning. Some such infants fail to thrive. They may stop eating and then waste away and die, a state called marasmus. Those who survive lapse into a phase of detachment, in which the infant withdraws from human relationships and becomes preoccupied with inanimate objects or his own body parts, engaging in masturbation, fecal smearing, head banging, and rocking.

In children of grade school age, the loss of loving parental figures tends to result in aggressiveness, hyperactivity, self-injury due to frequent accidents, inattentiveness in school, fire setting, and enuresis.

Many youngsters enter adolescence with a sense of loss relative to the simplicity of their previous life. Reactions of depression in adolescence are common. Sexual acting out is more often an expression of loneliness than of lack of morality. Because of his great vitality, the depressed teen-ager tends to act out not only sexually but antisocially. Juvenile delinquency, aggression, and reckless driving may be compared to the phase of protest previously mentioned. Suicidal threats and actions are used more to coerce adults than with deliberate self-destructive intent. However, successful acts of suicide are encountered with increasing frequency in the late teenage period.

Corresponding to the phase of detachment in early childhood is the "so what?" reaction in adolescence. An attitude of cynicism reinforces antisocial attitudes. Feelings of hopelessness, emptiness, and purposelessness may lead to addictions of all kinds. In

fact, addictions—whether to alcohol, narcotics, other drugs, food, or even the company of other people are typical adolescent expressions of the effort to overcome feelings of depression.

In adult life and thereafter, the picture of depression comes to resemble the picture of mourning more closely. In speech and behavior, the patient who expresses his helplessness often succeeds in recruiting support from the environment. In this context, suicidal threats and gestures are commonly employed as measures of protest or coercion.

Many fragile people maintain a marginal adaptation in highly supportive relationships in marriage or friendship. When these are disrupted, severe depression may emerge, which proceeds through all the phases: protest, despair, and detachment. Suicidal threats and gestures may occur during the reaction of protest. Alcohol, barbiturates, and other sedative drugs may be used to overcome feelings of despair.

A defense mechanism for dealing with the lost loved one is to act like that person, to adopt his interests, mannerisms, and way of life. This process is referred to as introjection. It is a form of identification that is potentially pathological in that it is often the result of feelings of helplessness and loneliness. Very commonly, depressed patients complain of symptoms that precisely reproduce the physical complaints of the deceased.

In a case of transvestitism (a compulsion to dress in the clothing of members of the opposite sex), a male patient periodically dressed in female attire as a way of retrieving his deceased mother.

A state of chronic depression may go on for years, with a progressive decrease of interest in the outside world. This intensifies the attention paid to the body, with a tendency to hypochondriasis. In later years, there may be an overlay of organic factors from cerebral arteriosclerosis, which complicates the clinical picture and renders the prognosis more grave. The reduction in energy output in depression also fulfills a self-preservation function in that it reduces the likelihood of self-destructive acting out.

Thoughts of self-destruction may occur transiently at one time or another during life within the limits of normal behavior. On the other hand, all verbally expressed suicidal thoughts must be given serious consideration, particularly where there is depression and there seems to be no promise of relief. In many instances, suicidal behavior represents a cry for help or an effort to induce protective behavior from an indifferent environment. With increasing age and progressive exhaustion of the reservoir of potential environmental helpers, the incidence of successful suicide goes up. Incidence of suicide rises uninterruptedly throughout life with males but tends to level off in the 7th decade with females.

Aggression. Aggression is forceful, goal-directed action that may be physical or verbal. It is the motor counterpart of the affect of rage, anger, or

hostility. It may be realistic and healthy, thereby representing self-assertion, directed toward the external world or turned inward, resulting in impulses or acts of self-destruction. Aggression is constructive when it is problem-solving and appropriate as a defense against realistic attack. It is pathological when it is unrealistic, self-destructive, non-problem-solving, and the outcome of unresolved emotional conflict.

Rage tends to emerge whenever strong drives are frustrated. In early childhood, separation from the mother, which is experienced as frustration, tends to generate rage as well as anxiety. The need to share the mother with the father is a universally encountered frustration and provides the basis for the Oedipus complex. The need to share the mother's love with siblings also creates frustration and reactions of rage: sibling rivalry.

Uncontrolled rage in early childhood may result in loss of mother's love and incur punishment. As a result, the youngster growing up in the framework of normal family life experiences great pressure to control outward expressions of rage. To a considerable degree, the psychological developmental process involves the increasing capacity to control rage and to find substitutive outlets for it. Conversely, loss of control elicits feelings of guilt and anxiety.

Where there is family disorganization, particularly in the socioeconomically deprived group which is characterized by broken homes and absent fathers, the capacity to control outward expressions of rage is impaired. In such a population, the incidence of suicide due to inwardly turned rage is low, while the occurrence of assaultive behavior and homicide is high.

In pathological mother-child relationships, a spectrum of rage reactions may be discerned with postpartum depression and suicide at one end of the scale and child battering and infanticide at the other. There are innumerable intermediary ambivalent mothering reactions, resulting in infant neglect and failure of the youngster to thrive physically and emotionally.

Psychiatric symptom formation has as one of its primary goals the control of forbidden aggressive impulses. Phobias, hysterical paralyses, and hysterical fugue states are common examples of this type of defense. Obsessive-compulsive symptoms may develop as devices for expressing aggression in a diluted form. Typically, even these "modified aggressions" generate so much guilt that the obsessional patient feels compelled to *undo* the aggressive act by means of a variety of complex compulsive rituals. Pathological states of apathy and boredom may result as a defense against rage. In some patients, a small quantity of alcohol may suffice to precipitate an attack of pathological alcoholic intoxication, which is characterized by an outburst of homicidal fury. Morbid fear of death may be the result of a chronic fear of loss of control of aggression, with a concomitant anticipation of retaliation from the environment.

Rage, unexpressed because of guilt and fear of retaliation, has been hypothesized to result in a variety of physical symptoms involving various organ systems of the body in psychosomatic disease. Homicidal rage may occur episodically in postepileptic twilight states. Aggression verbally expressed may take the form of obscene speech, and the defense against this may take the form of stuttering or hysterical speech disturbances.

Irritability refers to a state in which chronic diffuse expressions of anger occur to ward off relationships viewed as threatening. This may be found in paranoid character disorders, various psychoneurotic reactions, and the early stages of psychotic depression and schizophrenia. It is commonly encountered in adolescents to ward off sexual feelings felt toward parents and siblings.

Outbursts of rage with delusional ideation may occur in schizophrenia as a defense against unconscious homosexual impulses or other impulses consciously unacceptable. Violence

associated with criminal acts of breaking and entering may be encountered with perverse sexual impulses. Uncontrollable compulsive acts such as kleptomania, pyromania, and gambling may be masked expressions of rage. A major cause of suicidal behavior in depression is rage turned against oneself. In these instances, suicide becomes an internalized act of homicide.

Aggression merges with erotic thought and action in sadism and masochism. Sadism is the experience of pleasure derived from inflicting physical or psychological pain on others. Masochism is defined as pleasure derived from physical or psychological pain inflicted on oneself. Sadism and masochism may occur unconsciously within the limits of normal behavior as well as in sadistic or masochistic character disorders and in some psychoneurotic and psychotic reactions. These tendencies may also occur consciously in various sexual perversions, such as flagellantism, a masochistic or sadistic act in which one or both participants derive erotic stimulation from whipping or being whipped. Masochistic reactions are associated with unconscious guilt feelings, in response to which punishment is sought or invited.

Pleasurable affects. Implicit in the description of anxiety and depression are converse states, in which danger is absent and union with loved ones is perfect. In such a setting, the pressure of one's wishes and needs is balanced by the availability of adequate channels for impulse or drive discharge, and contentment prevails.

In infancy and early childhood, hunger and fatigue may rapidly transform a contented child into one who is fretful and unhappy. In the course of biopsychosocial maturation, the individual develops an increasing range of substitutive outlets and the capacity to delay immediate gratification. As a result, the capacity for affect stabilization increases. In the emotionally mature adult, there is an underlying stability of good mood that withstands the undermining traumata of daily life. The chronic absence of good feeling, anhedonia, is seen in chronic depressive states and in simple schizophrenia.

Normal recreation may be cited as an example of a substitutive outlet that allows for stabilization of mood. Recreation is characterized by a quality of irresponsibility, spontaneity, enthusiasm, hilarity, euphoria, elation, and other relatively uncontrolled expressions of emotion. During play, the emotionally mature adult is permitted to become a "child" again. Not only is this socially approved, but the capacity to act childishly in a controlled setting is a distinct asset. In play, it is possible to vent aggressive feelings against one's opponent. Mounting excitement culminating in a victorious climax may represent sublimation of sexual drives. Repetitive motor discharge through playing games is a device for achieving motor mastery in the developmental process and for recalling the sense of triumph upon accomplishing motor competence in the adult. Thus, while there are regressive elements in normal play, they are always within limits set by the rules of the game. The capacity to regress while maintaining disciplined contact with reality is not only part of recreation but of the esthetic experience in general and has been referred to by Kris as regression in the service of the ego.

Euphoria refers to the first, moderate level in the scale of pleasurable affects. It has been defined as a feeling of emotional and physical well-being. When it occurs in a manifestly inappropriate setting, it is indicative of mental disorder. Although it is usually psychogenic, it may be observed in organic brain disease.

Elation may be thought of as a second level in the scale of pleasurable affects. It is characterized by a definite affect of gladness in which there is an air of enjoyment and self-confidence, and motor activity is increased. This affect belongs within the limits of normal life experience. Yet, it may be indicative of mental disorder when it occurs in a manifestly inappropriate setting.

Mood swings refer to the oscillations between periods of euphoria and feelings of depression and anxiety. To some degree, mood swings occur within normal limits throughout life. They may be more marked during adolescence. Another normal life situation characterized by mood instability is the premenstrual phase in women, which has been referred to as "the recurrent neurosis of women." Anxiety, excitability, and anger are common; other cases show fatigue, irritability, hypersensitivity, and weeping spells. In almost all instances there is some regression, as a result of which the capacity to delay immediate gratification of impulses is impaired, and frustration seems unbearable. In most adult women, the onset of menstrual flow is followed by emotional relief.

As Benedek has shown, hormonal influences undoubtedly play a large role in this premenstrual upheaval. However, psychological difficulties related to unresolved feminine identity problems may complicate the picture.

Ambivalence refers to the coexistence of antithetical emotions, attitudes, ideas, or wishes toward a given object or situation at the same time. Usually, only one attitude emerges into consciousness, the other remaining unconscious. Ambivalence is encountered in all instances of affective instability. Thus, it plays a role in the mood swings that occur within normal limits. However, it is fundamental in many pathological mental states, being particularly prominent in the obsessive-compulsive, manic-depressive, and schizophrenic reactions. Bleuler regarded marked ambivalence as one of the primary symptoms of schizophrenia.

Various pharmacological agents may induce euphoria or elation. Alcohol, narcotics, and the amphetamines may be cited as examples. Underlying most cases of addiction is an anxious-depressive state that drives the patient to use agents which will relieve the painful affective states. These substances enable the patient to repress or deny the existence of painful affects. Brain lesions may have a similar impact on painful affects.

It was once thought that lesions of the frontal lobe specifically elicited a mood of euphoria. It is now known that any

brain lesion—anywhere and from any cause—that lowers the level of consciousness can have this effect. A small lesion involving the floor of the third ventricle may have a greater mood-elevating effect than a much larger one occurring elsewhere. Affability encountered in patients with senile dementia is an example of mood elevation associated with diffuse organic brain disease.

So far the role of drugs and toxic and organic factors as affect-elevating agents has been emphasized. Some patients are able to eliminate from consciousness painful affects without the aid of chemical consciousness-impairing agents by utilizing defense mechanisms that are exclusively psychological. They deny not only depression but all object losses as well. The manic patient does not feel deprived; he feels elated. In place of pessimism and despair, he has feelings of unwarranted optimism and self-confidence, and he is physically overactive and high-spirited. He feels that he has unlimited resources and, as a result, squanders money with reckless abandon. This pattern is called the manic reaction, or mania. When less intense, this behavior is described as a hypomanic reaction. Because the clinical picture represents a complete break with reality, without awareness on the part of the patient, such reactions are defined as psychotic.

Often the manic reaction thinly disguises an underlying depression by which it may be abruptly replaced. Manic reactions tend to be relatively short-lived and are typically followed by depression, hence the term manic-depressive or cyclothymic psychosis. In some instances, a hypomanic reaction may be indefinitely prolonged.

Exaltation may be defined as extreme elation and is usually associated with delusions of grandeur. It merges into ecstasy, which represents a peak state of rapture. These affects in inappropriate circumstances are found almost exclusively in relation to psychosis, such as the schizophrenic reaction.

The ecstatic states occurring in acute schizophrenia are related to the ecstatic transports of religious mysticism. The mystical experience, whether religious or not, possesses certain distinguishing qualities:

1. **Ineffability.** The subject often insists that his experience is inexpressible and indescribable, that it is impossible to convey what it is like to one who have never experienced it.

2. **Noesis.** The subject has the feeling that the mystery of the universe has been plumbed, that an immense illumination or revelation has occurred. Along with this may go a curious sense of authority, the conviction that one is privileged to lead and to command. As for the revelation itself, it seems to consist of layer upon layer of truth that, as it unfolds, may find expression in some familiar or even commonplace thought that suddenly seems pregnant with new meaning. On occasion, the expression of the truth may take the form of a document of poetic beauty and great moral significance, such as are represented by the writings of the biblical prophets. On the other hand, the revelation may be expressed in words that are unintelligible to the speaker.

3. **Transiency.** The actual mystical state may last only a moment, or it may go on for an hour or two; but when the experience ceases, the particular quality of feeling it aroused is only imperfectly reproducible in memory. Yet it is as un-

forgettable as it is highly treasured, and it colors all subsequent activity.

4. **Passivity.** In the mystical state there is an abeyance of the will, as if the subject were in the grip of a superior power to whose direction he is highly responsive.

5. **Unio mystica.** There is a sense of mystic unity with an infinite power, an oceanic feeling in which opposites are reconciled, in which there are "darknesses that dazzle" and "voices of silence." There is a quality of timelessness, in which minutes and centuries are one and in which past and present are one.

The mystical experience seems to represent psychological regression at its most extreme. It has been hypothesized that it is a retreat to the very beginnings of conscious psychological life, and in a sense it is an ultimate counsel of despair. As the individual travels backward in memory in search of a time when life was endurable, finding no one on earth to whom he can turn for help, he comes at last to a time of contentment that preceded conscious awareness of other human beings. It is a retreat to a time when infant and mother were fused. In recapturing this mood, the individual may find in the mystical experience a way out in the form of psychosis or a compelling religious experience, whatever its nature, that may be life-saving in its impact on the subsequent behavior of a despairing human being.

Mechanisms for maintaining mood control. The euphoric, manic, and ecstatic states are often based on painful affects, which are replaced in consciousness by their opposite. Other ways in which painful affects may be brought under control follow:

Depersonalization. This is a mental phenomenon characterized by a feeling of unreality and strangeness about oneself. The patient says, in effect, "This experience does not hurt *me* because I am not *me*."

The term depersonalization includes feelings of unreality, estrangement, amnesia, multiple personality states, and distortions in the body image. Depersonalization may be partial or complete, transient or long-lasting. It may be encountered in hysteria or as part of the aura of epilepsy. In schizophrenia it is complete and lasting.

Derealization. This is a mental phenomenon characterized by the loss of the sense of reality concerning one's surroundings. The patient says, in effect, "This environment is not dangerous to me because this environment does not really exist."

Derealization includes distortions of spatial and temporal relationships so that an essentially neutral environment seems strangely familiar (*déjà vu*) or strangely unfamiliar (*jamais vu*) or otherwise strange and distorted. Like depersonalization, to which it is closely related, derealization can be partial or complete, transient or long-lasting. Similarly, it may occur in hysteria or as part of the aura of epilepsy. It, too, is most complete and persistent in schizophrenia.

Although depersonalization and derealization occur as adaptational mechanisms to reduce unpleasant affects, they may in their own right create a feeling of impending catastrophe.

A feeling that could be shattering if experienced in a single episode becomes tolerable if "digested" piecemeal over an extended period. The traumatic neuroses of wartime may be cited as an example. An experience capable of generating overwhelming terror may be dealt with at the moment of occurrence

by depersonalization and derealization. When the catastrophe is over and the individual is no longer in danger, delayed reactions of anxiety may appear. Sleep may be disturbed by recurrent battle dreams. There may be an intolerance for sudden loud noises and for displays of aggression. After memories of the traumatic incident have been "revisited" repeatedly and the anxiety slowly mastered in small doses, the traumatic neurosis subsides.

Disturbances in Motor Aspects of Behavior

Conation, or the conative aspect of mental functioning, refers to the capacity to initiate action or motor discharge and concerns the basic strivings of an individual as expressed through his behavior. The affective component of an idea determines the force and the direction of the action that follows that idea. Thus, conation cannot be considered apart from affects, and, conversely, all affects represent potential energy via their conative components.

The schizophrenic seems to have a basic impairment of the conative capacity. He has difficulty initiating goal-directed activity. He may in some instances be capable of carrying on useful work if it is initiated for him and carried out under constant supervision, as in a sheltered workshop. Other examples of impaired conation in schizophrenia follow.

Echolalia is the pathological repetition by imitation of the speech of another person. In certain instances of catatonic schizophrenia, all speech is echolalic in nature.

Echopraxia is the pathological repetition by imitation of the movements of another person. The patient may act as the mirror image of his physician and assume his postures and gestures. Echopraxia is characteristic of catatonic schizophrenia. Waxy flexibility (*cerea flexibilitas*) is the maintenance by a patient of imposed postures with increased muscle tone, as when a limb remains passively in the position in which it is placed, however long or uncomfortable. This phenomenon may be induced during a hypnotic trance (catalepsy) in essentially normal individuals, but it is most characteristic of catatonic schizophrenia and organic brain disease. It is to be differentiated from cataplexy, which refers to a sudden, transient attack of muscular weakness, with or without loss of consciousness. Narcolepsy is paroxysmal sleep associated with cataplexy.

Echolalia, echopraxia, and waxy flexibility are cited as examples of command automatism, wherein commands or suggestions are automatically and uncritically fulfilled. Disturbances of motor activity may also be conveniently classified in terms of overactivity and underactivity.

Overactivity. Some individuals are endowed biologically with a tendency to increased motor output, which can be demonstrated in studies of fetal movements antepartum. The hyperkinetic child is particularly prone to restlessness, aggressivity, destructiveness, and assaultive activity during periods of family disorganization and emotional deprivation. Patho-

logical overactivity in childhood is particularly prevalent among boys. As they develop motor skills, boys become increasingly involved in athletic activities, which offer an opportunity for self-discipline and goal direction in the expression of their intense motor drives. Children may also develop hyperkinesis as a sequel to organic brain disease such as encephalitis.

Agitation is a state of chronic restless motor activity that is a manifestation of emotional tension. When a patient is restless and depressed, his diagnosis is agitated depression. The restlessness and uncontrolled motor activity associated with certain ataractic drugs such as the phenothiazines is called akathisia.

Learned sphincter control, which is part of motor development, may be lost during periods of stress. Thus, previously toilet-trained youngsters may become enuretic or encopretic during periods of enforced separation from the mother.

Patterns of hyperkinesis that start during the grade school period may carry over into adolescence and are, in part, the basis of antisocial behavior during this period. Thus, adolescent tendencies to reckless driving and sexual acting out, which have far reaching social implications, are best understood and treated as manifestations of biopsychosocial stress. Overeating, excessive drinking, smoking, irritability, and restlessness may also occur as fragments of the anxiety and depression syndrome in the adult.

Patterns of increased motor activity can be observed in the psychoneurotic reactions. The hysterical convulsion, for example, also known as major hysteria or hystero-epilepsy, consists usually of pantomimic expressions of sexual and aggressive fantasies. Occasionally, a hysteric patient may mimic a grand mal seizure with extraordinary fidelity; the major differential diagnostic feature is the patient's failure to develop postseizure reflex abnormalities.

Sleep-walking (somnambulism) is a motor disturbance that occurs primarily during childhood and tends to occur more often in individuals prone to hysterical symptom formation. It is also commonly associated with enuresis. On a psychological motivational level, it seems to be related to nocturnal feelings of fear and loneliness and the wish to enter the parental bed. In spite of what seems to be a simple mechanism at work, in which a child acts out relatively superficial wishes in a half-waking state, sleep-walking (as well as sleep-talking and enuresis), when monitored electroencephalographically, appears to take place during stage IV sleep, a period of deep sleep during which dreaming rarely if ever occurs.

Psychoneurotic reactions of the obsessive-compulsive type are characterized both by obsessive ideas and doubts and by complicated compulsive rituals. The range of compulsive actions is literally limitless, although certain patterns tend to occur most frequently, such as compulsive hand washing, counting, and repetitive ceremonial rituals, including the reci-

tation of prayers and the repeated checking of door locks, water faucets, gas jets, and windows. In each instance, the compulsive symptom simultaneously carries out a forbidden wish and then undoes it. The endlessly repeated cycle of anxiety, the need to carry out the forbidden act, relief of anxiety by carrying out the compulsive act, and the need to undo the act, characterizes the compulsive symptom.

Various compulsive manias are, in effect, pathological preoccupations or compulsions associated with specific ideas, activities, or impulses. For example: dipsomania, the compulsion to drink alcohol excessively; egomania, the pathological preoccupation with self; kleptomania, compulsive stealing; megalomania, preoccupation with delusions of great power; monomania, the preoccupation with a single idea; nymphomania, excessive sexual desire in a female; pyromania, the morbid compulsion to set fires; trichotillomania, the compulsive pulling out of one's hair.

A tic is an intermittent spasmodic twitching of the face or other body part, repeated at frequent intervals and without external stimulus. Although there seems to be some relationship between tics and motor disturbances of conversion hysteria, the tic is more stereotyped and difficult to influence with treatment. Tics occur automatically and are not under conscious control. They seem to originate as an accompaniment to affect: sex, rage, anxiety, grief, triumph, or embarrassment. In time, they become affect equivalents, in the sense that there is repetitive discharge without conscious awareness of the original affective significance.

Maladie des tics is a disorder characterized by a facial tic, which may spread to involve the head, neck, and upper and lower extremities. The tic is associated with stereotyped gestures, echolalia, coprolalia (preoccupation with obscene words), and compulsive thoughts. It usually begins between the ages of 7 and 15 and is essentially incurable. The muscular movements begin in the face and extend to the rest of the body. The patient opens his mouth, spits, jerks his head, claps his hands, scratches, jumps, and dances. Articulation and phonation are affected, and barking noises are often made. The patient repeats certain words or phrases, frequently expressing compulsive ideas. There may be some accompanying organic changes, but the nature of the pathology is unknown.

Manic patients may talk, sing, dance, and joke with apparently inexhaustible energy and good spirits. In agitated depression, there may be crying, pacing, and wringing of hands. In catatonic excitement, the pattern of overactivity is extreme from a quantitative point of view and bewildering from the point of view of content. Talking, which may be loud and voluble, is in response to delusions and hallucinations. The talk may consist of endless repetitions of sentences or phrases, the meaning of which is obscure (verbigeration). The severe ambivalence char-

acterizing the schizophrenic process may result in great mood swings, ranging from abject terror to exaltation. There may be sudden eruptions of terror and rage, in response to which the patient may become homicidal. There may be moments of deep guilt and an urge for self-sacrifice, which may result in acts of self-mutilation. The excited catatonic patient may execute various gestures that have the intent of influencing the world by means of magical thinking. Catatonic excitement, because of qualitative intensity and a tendency to be prolonged, may result in severe exhaustive states, with dehydration, hyperthermia, and sudden death. The use of physical restraint tends to increase terror, intensify excitement, and increase the dangers of exhaustion and death.

Underactivity (psychomotor retardation). Just as there are individuals constitutionally predisposed to hyperkinesis, so there are others who react to stress with motor inhibition. In childhood and early adolescence, generalized patterns of inhibition and retreat tend to have a more grave clinical significance than they do in later years and suggest the presence of a schizophrenic process.

Simple depression, in contrast to the agitated depression, is characterized by the absence of anxiety and by decreased motor activity. There is a feeling of pronounced fatigue and great difficulty in initiating any activity, including speech. Responses to stimuli are slowed up on an ideational, verbal, and motor level. The patient's posture is expressive of the underlying affect of hopelessness and futility.

Hysterical motor disturbances can affect any of the voluntary muscle groups in patterns calculated to ward off forbidden sexual and aggressive discharges or to avoid situations of physical danger. They may present clinically as paralysis or muscular weakness (asthenia); abnormal posture, such as torticollis, camptocormia, pseudocontractures, and stiffness; gait disturbances ranging from hysterical paraplegia to astasia-abasia. The speech apparatus may be affected with aphonia, hoarseness, and stammering. Blepharospasm may occur in relation to forbidden scopophilic wishes. The muscular abnormalities of hysteria are usually associated with an increase in muscular tonus. If sustained, they may produce painful orthopedic and gynecologic disorders. For example, hysterical spasm of the muscles of the pelvic floor may cause vaginismus. Concerning the physical findings in hysterical paralysis, Freud wrote "The hysteric acts in his paralyzes and other manifestations as if anatomy were non-existent or as if he had no knowledge of it."

Although hysterical paralyzes are usually associated with increased muscle tone and rigidity, on other occasions a total flaccidity, except for the retention of normal reflexes, is encountered. On occasion, an attitude of ambivalence will express itself in variations in muscle tone.

In the schizophrenic catatonic stupor, the patient is immobile. His face may be masklike in its lack of animation. He is unresponsive to questions or commands except when he occasionally manifests echolalia or echopraxia. When an attempt is made to bend his arm at the elbow, he may vigorously extend it. He may close his eyes tightly when asked to open them. These qualities, which may be regarded as contrariness or countersuggestibility, are manifestations of a generalized oppositional attitude called negativism, wherein the patient does the opposite of what is requested. Ambivalence may modify the muscle tonus of the patient with catatonic stupor to the extent that he will permit bending of his arm but against a resistance, so that a tonus quality emerges known as waxy flexibility.

Motor disturbances may express themselves primarily in disorders of language. Stammering is a disorder characterized by spasmodic, halting or hesitating speech. Stuttering is a more severe degree of stammering. It tends to have a more explosive quality, based on violent expulsive respiratory movements associated with the production of speech. It usually appears between the ages of 2 and 6 years. It occurs much more frequently in males and is said to be more frequent in those who are left-handed.

When an individual encounters an affect-laden idea while speaking, he may hesitate and stammer. Such an interruption in the flow of words is analogous to a slip of the tongue and represents a momentary speech impediment based on an encounter with a circumscribed and personalized conflict. However, when the function of speech itself has acquired an objectionable emotional overlay, there is an ongoing disturbance in the capacity to speak more or less independent of the ideas themselves. Such is the situation in stuttering.

Disturbances of Personality

Personality refers to the sum total of the patterns of thought, feeling, and behavior that an individual habitually employs in his ongoing adaptation to life. Personality is often used synonymously with character. Normal personality implies a state of maximal fulfillment in terms of flexible adaptation to adult reality. For most people, however, personality development involves a process of becoming psychologically rigid and of making peace with one's own illogicalities, eccentricities, and follies. As a result of personality rigidity, there is a certain loss of freedom of thought and action. However, overt symptom formation is prevented thereby. The structural rigidities of personality often conceal deep-seated psychopathology. Under stressful conditions sufficient to disrupt these structures, severe symptom formation, including overt psychosis, may erupt.

Various personality disturbances may be distinguished and are described in detail in the chapters covering personality disorders. They include, to cite a few: inadequate personality, schizoid personality, cyclothymic personality, paranoid personality,

passive-aggressive personality, and compulsive personality.

The sexual perversions are also included among the personality disorders. Some of these are: homosexuality, pedophilia, fetishism, transvestitism, exhibitionism, voyeurism, sadism and masochism, and zoophilia.

Disturbances in Appearance

It is relevant at this point to discuss the relationship of appearance to the clinical manifestations of psychiatric disorder. Extremes of meticulousness or slovenliness and attire which is manifestly inappropriate or bizarre and which calls attention to itself for these reasons may all be indicative of mental disturbance.

Excessive fastidiousness may suggest an obsessive-compulsive disorder. Deterioration from a previous normal level of neatness may be an early sign of depression or schizophrenia. When a female patient seeks to arouse sexual desire by her seductive dress, make-up, and manner, hysteria should be suspected as an element in the clinical diagnosis. Male homosexuals are distinguished for their exhibitionistic attire. A sexually fearful female may deliberately choose neutral or drab clothing to discourage the interest of potential sexual partners. Regressive clinging to childhood may be expressed in childish patterns of dress. For example, a mature woman may wear a large ribbon in her hair.

Rejection of normal sexual identity is encountered in adolescent females who affect boys' haircuts and blue jeans and in adolescent boys who affect female or childhood hair styles. Repulsive body odors due to lack of bathing may be designated "the skunk maneuver," calculated to keep a frightening world at a safe distance. Paranoid patients may wear dark glasses so that they may "spy" on others without themselves being spied upon. Eccentric patterns of dress, including large unkempt beards and excessively tight pants, may become a badge of rebellion or a conformity for membership in teen-age groups.

Transvestites are sometimes acting out complex fantasies involving a wish to recapture a lost parent figure. Schizophrenic patients may first reveal the delusion of body change by complaining that a hat or a pair of eye glasses no longer fits properly. Powerful automobiles and other possessions may become extensions of the body image and serve to compensate for feelings of inferiority.

Life Pattern Disturbances

In the psychiatric evaluation of an individual, the main concern should be with actual life performance rather than with the symptoms he displays or the psychodynamics of each symptom. The important question is not whether he has psychopathology but whether the psychopathology "has" him. To evaluate an individual in operational terms, the psychiatrist

must make inquiry into four separate areas: family, work, play, and community. In each of these areas, the patient is expected to function in a specific role. The effectiveness with which he performs these roles is a measure of health, just as impairments in these areas are a measure of life pattern disturbances and mental illness.

Family. Within a family group, one can identify the following roles: (1) spouse (husband, wife), (2) parent (father, mother, grandparents), and (3) child (son, daughter, sibling).

Each of these roles involves a complex of capacities and responsibilities. The husband must be not only the wage earner but also the sexual partner and companion for his wife. The capacity for satisfactory sexual performance is implicit in his role. Potency disturbances can have a severe undermining effect on family happiness. Just as satisfactory sexual performance reinforces the male's concept of self as a man, the satisfactions he gives to his wife reinforces her identity as a woman and promotes acceptance of her female role. Ideally, from a psychological point of view, the husband should be the leader in the home. If he is unable to assume family leadership because of his personal psychopathology or because socioeconomic factors have displaced him from that role, he gets caught up in a vicious cycle that is destructive to both himself and the rest of the family.

The wife must be capable of accepting her feminine role both sexually and in her over-all responsibilities in the household. If she is frigid and incapable of sexual satisfaction in spite of normal sexual potential in the husband, this may undermine his self-esteem and have a destructive impact on his over-all performance. Thus, there is in the sexual life of the married couple a give and take in which there is mutual reinforcement of self-esteem when the sexual life is normal and mutual disturbance when it is not.

Perhaps the most important aspect of the parental role is the capacity to accept an attitude of passive dependence in others. There are periods of helplessness and dependency needs that fall within the range of normal, and a *sine qua non* for normal function as a spouse or parent is the mastery of one's own infantile dependency needs. A person who has achieved this is capable of providing maximal opportunity for normal emotional development in others. On the other hand, reversal of roles is often seen in disturbed households in which an emotionally immature parent makes unrealistic demands on a young child. A schizophrenic or depressed mother may take to her bed and expect her little daughter to mother her.

That the mother plays a role of special importance in the emotional development of the child is self-evident. However, the importance of the father in the developmental process is equally great. Not only does he consolidate the self-esteem of the

mother, but he provides an identification for the son and, in his relation to the mother, an identification model for the daughter. Families without fathers are particularly prone to psychopathology.

Grandparents play a complex role in family life, with variations that are determined largely by cultural factors. Perhaps the most important fact is that the grandparent role permits the individual to continue the reproductive role vicariously, with many privileges that are not possible with one's own children.

Children must develop basic security and basic trust in their relationships to their parents. Where the opportunity for this does not exist, attitudes of cynicism and distrust emerge and seriously impair the social, intellectual, and emotional developmental process. One result of effective parental participation in family life is the setting of limits on the outward expression of sibling rivalry. The birth of a sibling is universally experienced as a trauma, resulting as it does in a displacement of the older child from the bosom of the mother. The displaced youngster has feelings of rage, for which he needs help from his parents. If this help is not forthcoming, the youngster does not internalize his aggression or learn to sublimate it. Instead, he expresses it outwardly. This is why the likelihood of homicide and other forms of violence is greatly increased in communities characterized by family disorganization and absent parents.

Work. At each stage of life every individual has a work role. For the school age youngster, this involves his capacity to function as a student. The wage earner must be able to work with reasonable effectiveness and personal satisfaction. The same is true for the wife in relation to her household chores. Many people work far below their potential because of psychopathological work inhibitions. Some are self-defeating out of a sense of guilt. Others are self-defeating because of a fear of success (those who are destroyed by success). Some fall behind because they must rebel in their quest for identity. On a school level, this expresses itself as an impaired capacity for learning and in the school dropout problem.

Retirement from work may have a severe disruptive impact on the adaptational patterns in a family and may touch off a vicious cycle of psychopathology. Some people might be termed work addicts. These are guilt-ridden people who work compulsively and for whom loss of a job or retirement upsets a delicately balanced adaptational state; loss of work may at times result in severe mental illness and disruption of family life.

The chronic schizophrenic patient has a peculiar attitude to work. If he works at all, he chooses work settings that are highly structured and that permit isolation from other human beings. The postal clerk on the night shift occasionally is an example of this. Many schizophrenics refuse to work. In some instances at least, work is viewed as a threat to basic

security in the sense that success might mean separation from parent figures and loss of a sheltered home setting. For this very reason, some patients who fear to work for pay will work on a volunteer basis. The inability to hold a job carries with it a particularly poor prognosis in schizophrenic patients.

Social. Normal emotional development calls for a capacity to enjoy one's leisure. This involves not only a range of skills and interests but freedom from guilt and anxiety. The capacity for spontaneity, enthusiasm, and elation has already been mentioned in the description of normal recreation. Some people in recreational situations are like work addicts. They play compulsively, angrily, and anxiously. They are so demanding of themselves that they suffer severely if they make errors; if they lose, they become depressed. In these instances, the superego remains too much in control, and there is no opportunity for genuine sublimation.

Community. A concern for the welfare of others should extend beyond the confines of the family. The emotionally mature adult has a sense of duty toward his community and ideally involves himself in charitable, educational, or political groups to provide service to others without financial reward. This involves a capacity for idealism and self-sacrifice and the ability to get along with others. Needless to say, many become involved in this area for pathological reasons, such as guilt, exhibitionism, and a need for self-aggrandizement. In such instances the formal goal of the group may clash with the pathological informal goals of the individual. If such individuals have positions of leadership, they may exert a highly destructive influence on the group, which may necessitate their removal if formal group goals are to be achieved.

Suggested Cross References

The reader is referred to the sections dealing with the psychiatric examination (Chapter 11) and psychological testing (Sections 12.1 and 12.2) for information regarding the techniques of psychiatric assessment that are designed to elicit and identify the various psychiatric symptoms described in this chapter. For a further understanding of the implication of the symptoms covered in this chapter, see the discussion of the specific disorders in which these symptoms occur, which may be found in Area F, on psychiatric disorders, and Area H, on child psychiatry.

THE PSYCHIATRIC SYNDROMES

This area addresses itself to discussion of those clinical syndromes which fall within the province of psychiatry. As such, it deals with disorders of diverse etiology which share in common the fact that their clinical manifestations involve disturbances of psychological functioning. In essence, this area has been organized according to the official nosological system of the American Psychiatric Association. However, any such attempt to organize psychiatric clinical entities must, inevitably, reflect the problems intrinsic to diagnosis and classification in this specialty. These problems are discussed in detail in Chapter 14 of this area; an overview of the major issues involved is presented below for purposes of orientation.

Historically, the classification of syndromes associated with a predictable outcome, on the basis of clusters of clinical symptoms, represented a major advance in psychiatry. Kraepelin's delineation of dementia praecox—the syndrome now identified as schizophrenia—as distinct from other forms of psychosis was a crucial contribution toward this end. Equally significant was Freud's concept of the "defense neuroses" as a single diagnostic category which encompassed clinical disorders with widely divergent symptomatology, such as hysteria, obsessive-compulsive reactions, and phobias, which had previously been regarded as unrelated disorders; furthermore, this formulation led to important therapeutic advances, as well as conceptual clarity. Nevertheless, despite the fact that it reflects such major achievements, it is the general consensus of professional opinion that the system of psychiatric nosology in current usage is not entirely satisfactory. Its limitations derive primarily from the fact that the etiology of many psychiatric disorders is not fully understood as yet. Thus, while the current nosological system is based on the description and classification of the clinical manifestations of

psychiatric syndromes, these syndromes are not always associated with reliably predictable outcomes; nor does the system always facilitate choice of treatment. In an effort to surmount these defects, many other systems of classification have been proposed as possible alternatives. For the most part, these are based on various controversial assumptions regarding the etiology of mental illness and employ criteria which range widely, from degree of social disability, at one end of the continuum, to response to drug therapy, at the other.

Admittedly, the limitations of our present nosological system are serious. Unfortunately, however, none of the alternate proposals made to date appears to offer any striking advantages over the system presently in use. For one, it is self-evident that a uniformly accepted psychiatric "vocabulary" is a prerequisite for purposes of communication. If we dispensed with a uniform nosology, the veritable Tower of Babel which would certainly arise in its place would surely disrupt research, epidemiological studies, and efforts to teach and communicate the skills of psychiatry.

In light of the foregoing considerations, Area F has been organized into chapters which deal with adult psychoses, brain disorders, psychoneuroses, personality disorders, psychophysiological reactions, and mental retardation—as delineated in the official nomenclature of the American Psychiatric Association. In addition, however, several disorders which are not presently included in the official nosology but which, nevertheless, are of interest and importance are described. These include "exotic" psychotic states, such as latak and amok, which are seen in cultural settings other than our own, as well as clinical entities which are commonly encountered in our society, such as postpartum disorders, hypochondriasis and neuroasthenia, and nonpsychotic cyclical depression. Another chap-

ter within this area is devoted to the description and discussion of psychiatric emergencies, such as suicide, homicide, and other forms of violent behavior, and states of acute intoxication which are accompanied by dangerous behavioral manifestations. These syndromes may cut across various diagnostic categories; they are presented under a single rubric herein, by virtue of the fact that they share in common an urgent need for immediate psychiatric intervention.

For purposes of clarity and comparison, the discussion of each of the clinical entities presented has been organized, insofar as this was feasible, to include the following topics: definition; epidemiology; clinical description (including symptoms, course, laboratory findings, differential diagnosis, and prognosis); etiology; and treatment.

As might be expected, in some instances, the subjects of etiology and treatment must pose a problem for the editors of a psychiatric textbook which attempts a comprehensive and eclectic presentation. For example, although many different hypotheses have been advanced to explain the etiology of the so-called "functional" psychoses, such as schizophrenia and the depressive psychoses, no single formulation is universally accepted. In this book an attempt has been made to review those hypotheses which appear to have scientific merit, without commitment to any specific viewpoint.

To illustrate, the section which deals with the etiology of schizophrenia reviews a wide range of hypotheses which might be categorized as follows. A growing number of hypotheses emphasize the importance of biochemical, genetic, or physiological factors in the predisposition to and/or precipitation of this disorder; a second group of psychodynamic theories rests on the assumption that disturbances in the patients' early psychic development are operative in the genesis of schizophrenia; other formulations attribute schizophrenic disorganization to disruptive factors in our society; and, finally, still a fourth group of authors postulate a unified view in this connection. More specifically, according to this last viewpoint, distortions in early development, adverse environmental and experiential factors, and disruptive elements in society

will combine to produce a schizophrenic person when there is a genetic predisposition to this illness.

The fact is that even the dynamics of those disorders which are presently ascribed primarily to psychogenic factors, such as neurotic reactions and personality disorders, are subject to controversy. These differences among psychiatrists in their interpretation of the psychodynamics operative in the disorders in question derive, in turn, from the fact that no single theory of psychopathology is universally accepted. In keeping with the eclectic orientation which we have tried to maintain throughout this volume, the chapters dealing with these syndromes encompass sections by authors of diverse theoretical persuasions.

At times, this current diversity in theoretical orientation is reflected in corresponding differences in treatment orientation. For example, an author who feels that there is a primarily organic determinant operative in depressive reactions will tend to advocate electric convulsive therapy as the treatment of choice for this patient population. In contrast, those authors who attribute depressive illness to early disturbances in object relationships would be expected to employ psychoanalysis, when feasible, or some form of psychotherapeutic intervention as the ideal treatment modality. Within each section, each author has discussed the specific disorder or disease category under consideration according to his own particular theoretical (and therapeutic) predilection. In addition, in order to ensure comprehensive presentation, each author has indicated the existence of alternative theoretical viewpoints and has attempted to review the various forms of treatment which are traditionally employed in the disorder under discussion.

Specific psychiatric syndromes are the focus of discussion in this area, and general information regarding techniques of psychiatric diagnosis and descriptions of the various psychiatric symptoms may be found in Area E, on psychiatric assessment. In addition, the various treatment modalities described herein with reference to specific syndromes are discussed in detail in Area G, which deals specifically with psychiatric treatment. Finally, this area is limited to discussion of psychiatric disorders in adults; psychiatric disorders in childhood are discussed in Area H.

Chapter 14

Classification in Psychiatry

14.1 NOSOLOGY

HENRY BRILL, M.D.

Psychiatric classification is in many ways a deceptively simple matter. It can be carried out routinely by using less than 50 of the 132 pages of the American Psychiatric Association's *Diagnostic and Statistical Manual*, and a number of national systems are far shorter. It is surprising how quickly the average resident in training can learn to comply with the formal requirements by using one of these outlines as his main guide.

On somewhat closer examination, this seeming simplicity proves illusory because psychiatric classification approximates a kind of maximum condensation of contemporary psychiatry and embodies theoretical and practical implications of the utmost complexity. Exploring these can lead one into such collateral problems as communication theory, the science of systematics, the philosophy of science, the history of psychiatry, and the complex problems central to psychiatric nosology itself. Obviously, most of these topics can be barely mentioned in a review of this kind, but they cannot be completely ignored, since they are a part of the total perspective.

Classical Background of Classification Theory

Many current issues in psychiatric classification are neither new nor specific to the field, although, if seen as purely psychiatric problems, they do appear to be specific and perhaps subject to simple solutions. An interesting example is the often repeated proposal that *all* psychiatric classification be abolished, on the ground that there are only quantitative differences among the disorders of various individuals and that all cases are *different* and, therefore, cannot be grouped but must be described individually.

It is difficult to avoid the impression that this is a replay in modern dress of a controversy that extended from the 11th to the 14th century, when a bitter debate raged around the idea that all collective terms, such as animal, man, wood, stone, had no existence or

reality and were mere words. The argument originated in Aristotle's "Categories," which propounded the problem of genera and species and which split Scholastics into three warring groups. This analogy may seem far fetched, but it serves to recall that classification involves a very subtle and complex logic, although it is basic to even quite simple human thought. Common language itself is made up of classifications developed in a long forgotten past, and Aristotle, as founder of the science of logic, gave classification a central place in it.

The heat of the discussion of the Scholastics arose not from the abstract merits of the issues themselves but as a displacement from certain very practical religious implications. Similarly today, there is considerable displacement of affect from certain practical implications of psychiatric classification onto the classification itself. Although this is quite human and understandable, it is not helpful in arriving at a scientific solution. In any case, it appears futile to speak of abolishing classification, unless one were to give up all generalization and communicate only in the most concrete, individualistic terms. In view of this, the question is not whether or not we shall have classification but rather what *kind* or *kinds* will best serve our purposes. The answer depends entirely on what our aims are.

Purposes of Classification

In general, classifications are a device for reducing complexity by noting the similarities in a given mass of observations and then grouping them abstractly in order to deal with them more easily as a conveniently small number of things. A multitude of concrete observations must be brought to some kind of order and simplification if they are to constitute a subject of effective communication that can be handled by logic or if they are to serve the needs of knowledge.

There is, of course, no one absolute means of arranging objects. They may be grouped in many different ways depending on the purpose of the moment. For instance, water may be classified according to size (from puddles to oceans), temperature (from steam to ice), or purity (from pure to infected). Each

classification is valid and useful for a particular purpose or interest, though each is made up of quite arbitrary points on a continuum, and not one is composed of entities with absolute differences.

In clinical psychiatry, classifications serve important functions with respect to education, treatment, professional communication for recording and retrieval of data, research, and administration.

Definitions

Classification is a specialized science and a branch of logic with its own history, terminology, and definitions, and it has various subspecialties, of which psychiatric nosology is only one. A review of several of the important definitions is necessary here because various authors use terms in somewhat different ways.

Classification. In medicine the term classification refers to a specifically ordered arrangement of selected terms in which various disorders are gathered into groups, and these in turn are gathered into larger classes, which in their turn are finally drawn into major categories. Thus, in the American Psychiatric Association (A.P.A.) classification, catatonic schizophrenic reaction is a subdivision of schizophrenia, which is one of a family of psychoses, and this is, in turn, a member of the subdivision called "disorders of psychogenic origin." The purpose of the classification is to create groupings based on significant similarities among the properties and peculiarities of the items being arranged. Thus, the disorders gathered under the heading of "psychoses" are thought to have characteristics in common that distinguish them from those found under "neuroses."

Any particular classification must be like a sorting rack for experience, with one specific position for each type of case, including the unclassifiable and the partially unclassifiable. Individual terms may be, and usually are, part of a nomenclature or terminology; but the way in which the terms are grouped and arranged turns the list into a classification. There is some reason to consider the identification of entities as different in nature from the arrangement of entities into larger groups that correspond to genera and species, but this has not been widely accepted in psychiatry.

Artificial and natural classifications. When the products of human experience are arranged, satisfactory underlying principles are often lacking, and it becomes necessary to use arbitrary groupings based on superficial characteristics, as when patients are classified according to economic disability. Such a classification is called artificial. In some discussions of psychiatric classification, the assumption seems to be that this is unscientific and that the only acceptable form is the natural one, that is, some system based on a significant underlying characteristic. For example, a natural classification of disease would be by causes, such as infections, trauma, and prenatal influences.

The most advanced scientific classifications do today

reflect great natural laws. An example of such a classification is the periodic table of Mendeleev; but the vast inner meaning of this arrangement did not emerge until long after the arrangement had been devised on relatively superficial, or artificial, grounds. Another great natural law is that of evolution, which is linked to the classification of Linnaeus; but his classification is an outstanding example of the value of an artificial arrangement, since it preceded Darwin's work by a century and originated as a purely artificial grouping based entirely on external characteristics; its natural characteristics were not discovered until long afterward.

The major psychiatric nosologies are neither totally artificial nor totally natural. Their individual elements or entities did not originate from a single system but were each evolved separately in the course of a long history of cumulative observations. All important modern psychiatric nosologies show gradations from the clearly natural organic disorders to the clearly conventional wastebasket of the personality disorders, where much of our current lack of knowledge is gathered into one place. Yet the artificial elements are justified by the principle that a purely artificial and conventional system is far better than none at all, and must be used when a natural one is not available.

Nomenclature. An arrangement of the terminology specific to a science is called its nomenclature. The arrangement is arbitrary and often alphabetical and is independent of any underlying characteristics. There may be, and often are, overlapping among various terms and multiple names for a given object, although one is generally marked as "preferred." *Current Medical Terminology*, now published annually by the American Medical Association, is an excellent example that covers the entire field of medical practice, including psychiatry. It represents a bold and revolutionary attempt to create and maintain a codification of current usage, quite in contrast to the decennial revisions of the classification systems.

Nosology, taxonomy, and systematics. Specialists make various distinctions among these terms, but here they are considered synonymous with each other and with "classification."

Statistics, statisticians, and code numbers. Classification is as old as recorded psychiatry, but the current use of diagnosis for public health purposes can be fairly attributed to Florence Nightingale, who, with the medical statistician William Farr, first proved the devastating effect of well marshaled medical statistics in a battle for medical reform. Since their time, it has become increasingly clear that diagnosis cannot be a strictly individual and personal affair between patient and physician because of the overriding implications for public health and prevention. As a result, the mechanism for collecting such data has been much expanded and formalized.

Each item in a modern classification is accom-

panied by its identifying code number, and these numbers, arranged in a sequence, together form a system for sorting cases into various categories. Contrary to the impression that might derive from a hasty glance at these impressive looking columns of figures (some of which are hyphenated and run to six digits), there is no computational principle involved. They are purely for identification, analogous to numbers on license plates of automobiles, for convenience in sorting cases according to diagnosis, and for carrying on various statistical analyses. The special requirements imposed on the psychiatrist by statistical needs are relatively slight, and in no case do they impinge on his freedom to make an adequate diagnosis. They do not, however, permit making multiple diagnoses, all of equal value. Given half a dozen such terms in each case, the statistician would, because of the vast number of permutations, find it difficult to identify more than a small number of patients with exactly the same diagnosis in any sample of reasonable size, thus ruling out all statistical analysis of diagnosis. Of course, there are some investigators who feel that classification should not be subject to statistical analysis, but they are as yet in the minority and stand contradicted by a vast amount of work being done in terms of classification.

History of Classification in Psychiatry

It is fair to say that there has never been any psychiatric practice without a classification, and each classification represents a condensation of an entire system of psychiatric thought; thus, a history of classification would be equivalent to a history of psychiatry. This section is limited to a review of some of the relevant and interesting facts.

In spite of many deviations and retrogressions, the record is one of cumulative observation, with gradual evolution of concepts and clarification of thinking over more than 4,000 years. Traces of the evolutionary process survive in current psychiatric terminology, and the evolution has been in part a reflection of advances in knowledge. In addition, there are other influences—social and religious influences, political conditions, and the state of general technology. Finally, time alone seems to bring changes in the language of psychiatry independent of external influences.

Early classification. The mental changes of old age were historically among the first to be clearly identified, although the differentiation between parenchymatous disease and cerebral arteriosclerosis had to wait for the development of histology at the end of the 19th century. Similarly, alcoholic mental disorders and deterioration were recognized in ancient times, in spite of the fact that distilled liquors were not invented until about 900 A.D. Curiously enough, opium was described in the earliest records, but addiction was not medically diagnosed until comparatively modern times, and the effects of abuse were not even mentioned until late in the Middle Ages.

From the beginning, a very important place was assigned to supernatural causes of disease, and these influences are still seen in current terminology. The term "obsession" survives as a memento of the time when it was thought that the mentally ill person was besieged by the devil from without—a less serious condition than "possession," where the devil was within the victim. Similarly, the term "alienated" originated with the same idea that the victim had alienated or given over control of his soul to the devil in barter, and the term is borrowed from business law.

Many modern entities have a history that goes back to ancient medicine. The homosexual was described by the Greeks under the name of "pathicus." The ancients recognized the deliria of fever, some depressive states, the patterns of epilepsy, and certain effects of brain trauma. They also showed considerable sophistication about the existence of psychosomatic influences, although these were limited to the more obvious autonomic reactions of pulse and the like. Malingering of psychosis was recognized, as was mental retardation in children. But there was much confusion of functional and organic disorders. Schizophrenia itself was not delineated until the 19th century, and the neuroses remained virtually unexplored nosologically until then.

Modern classification. Modern classification begins in the late 18th century. Historical accounts stress the great influence of Linnaeus, whose success with biological taxonomy stimulated a vast amount of nosological activity in psychiatry. This effort, however, proved to be of little value or effect. Numerous classifications of mental disorder were created, one such coming from the pen of Erasmus Darwin, the grandfather of the great naturalist. All these are of purely academic interest, and it was not until the development of asylums brought the mentally ill under observation of specializing physicians that psychiatric nosology entered into its modern phase of rapid development.

The first of these physicians was Pinel, who provided a very simple system based solely on his own observations; he refused even to discuss the arbitrary distributions of other nosologists. Although fully aware of the work of his predecessors and his contemporaries, he consciously imitated only the methods that had "contributed to the rapid advance of modern natural history." He described melancholia, mania without delirium, mania with delirium, dementia, and idiotism. However, hallucinations in our modern sense are not described in his 1806 edition. And although Pinel uses the engaging term "mental indispositions," he does not discuss the neuroses as we know them today, nor does he describe the mental changes of age, although he mentions them briefly.

Objective, long term observation in mental hospitals continued to support advances, which were accelerated by the use of the pathological laboratory, a German development that helped that country assume psychiatric leadership by the middle of the 19th century.

It was from there that Griesinger's influential nosology was published. He had a strongly organicist approach, in contrast to the antiorganicism of Pinel, and for several generations the work of the pathologists in the mental hospitals played a significant role in neuropsychiatry. The organic and exogenous psychiatric disorders were rapidly delineated, and the studies of Alzheimer, Nissl, Wernicke, Bonhoeffer, and the Russian Korsakoff made psychiatric history. The clinical work of Itard and Séguin clarified the question of mental deficiency and cleared the way for a better delineation of the functional mental disorders.

As a result, a new concept, *dementia praecox*, began to emerge. Thomas Willis had noted regressive changes in previously normal children 2 centuries before. Morel used the term in 1850, but without delineating the syndrome, and in 1870 Hecker and Kahlbaum described "katatonia." But it remained for Kraepelin, on the basis of his asylum experience, to pull together katatonia, hebephrenia, various dementias, *vesanias*, and certain "degenerations" to create the new concept of *dementia praecox*. This was later modified to schizophrenia by Bleuler, but the basic syndrome described by Kraepelin was widely accepted, as was his subsequent delineation of the manic-depressive psychoses.

The personality disorders (still the most unfinished of all the categories) had long been recognized in relation to law and literature but did not become a part of psychiatry until noted in "Moral Insanity," by Prichard.

The concept of the psychoneuroses is often considered to be of rather late development, and this is true of its modern psychodynamic form. However, the hysteria of the ancients certainly dealt with psychoneuroses, and a vast amount of out-patient psychiatry with psychoneurotics was done by the Mesmerists of the 19th century and by their predecessors, who had practiced magnetism and the laying on of hands for centuries. An extensive background of clinical practice thus existed for the systematic work of Beard in neurasthenia, Janet in psychasthenia, and Charcot in hysteria and, finally, for the great syntheses by Freud, whose classification of mental mechanisms cuts across all others and operates in its own independent dimension.

By the end of the 19th century, the main outlines of current nosologies had been laid down, for both descriptive and dynamic psychiatry. In the next 20 years, the marked variability in nosology that had characterized the previous century gradually came to be replaced by standardizations based on the categories just outlined.

Standardization of Nomenclature and Classification

Until relatively recent times, medical classification and nomenclature, including that of psychiatry, were local or even personal matters based on whatever authorities a physician was inclined to follow and on

whatever influences a hospital or medical school might bring to bear. The example of Florence Nightingale and others proved the importance of medical statistics, and it was inevitable that from then on uniformity and comparability of data should become a key issue in public health matters. A standardized international list of causes of death was first authorized in 1853, and in 1900, after the death lists had been revised many times, the causes of morbidity began to be developed. An eighth revision of this now standard work is in process under the aegis of the World Health Organization (W.H.O.). Most of the psychiatric disorders are found in one section of this publication, although some are scattered elsewhere in the classification.

In the United States the first move toward psychiatric standardization occurred in 1917, with a statistical classification of mental diseases prepared by the American Medical Psychological Association. In 1928 the American Medical Association first moved to adopt a general standard nomenclature of morbidity and death, and organized psychiatry undertook to prepare the section on mental disorders, which appeared simultaneously as a manual of the Association. This pattern has been retained through successive revisions at intervals of about 10 years, and the current A.P.A. manual dates from the 1952 revision.

Diagnostic and Statistical Manual of the A.P.A.

Adopted in 1952, the current manual of the A.P.A. represents the most radical of the revisions to date. It sought to meet the objections that previous listings had been based purely on the experience of mental hospitals and were not suited to out-patient psychiatry or even to the psychiatry of the short term, acute psychiatric unit of a general hospital. The manual drew heavily on the experiences of World War II and on private practice; it reflected the very important position of psychodynamic concepts in American psychiatry. As a result, the A.P.A. classification is different in terminology and in certain aspects of orientation from systems used elsewhere in the world, but, as appears very clearly in Stengel's review of current systems, the points of similarity are even more important; this is not surprising, in view of the fact that all such systems stem from a common psychiatric literature.

Advantages. Among the advantages of this A.P.A. standardization, the following may be listed: (1) It has achieved a far wider acceptance and use than has been the case with any other system, a fact of the utmost importance if it is to have meaning as an instrument of professional communication and of public health policy. It has now entered the literature extensively and has been the vehicle for a large amount of publication. (2) It contains a succinct and clearly defined syllabus that defines and delineates the various disorders. (3) It is easily convertible to the W.H.O. classification and contains convenient tables that pro-

vide the equivalent terms for these systems and for the 1942 edition of the A.P.A. manual. (4) It contains clear operating instructions for statisticians and hospital librarians to facilitate reporting and preparation of uniform data. (5) It gathers all terms necessary for psychiatric classification into one manual and does not scatter them over a much larger, general medical classification. (6) It is sufficiently simple to be used in average hospital practice, and its formal characteristics are such that the data produced are suitable for statistical analysis.

Each of these characteristics is important for a national system of classification and will have to be improved upon or at least equaled by any system that might replace it.

Criticisms. Since the criticisms of current classifications are many and range from abstract, conceptual differences to simple operating problems, it is difficult to select among them for discussion, as each has its own relevance. Some urge that mental disorder is different from physical disorder and that mental disorders deal with differences in degree and in amount of psychopathology rather than with different entities of disease.

The essence of this argument seems to be that the classification is artificial and not natural; but even completely artificial systems may be useful when the basic concepts underlying the manifest differences have not yet been clarified. However, it is true that such criticisms often accompany elaborate replacement proposals, and it remains to be seen if one of these will eventually emerge as more useful and more effective than the methods that now exist. Perhaps it might be better to consider such proposals, in part at least, as an effort to provide additional methods of classification in a field so complex that no one system is adequate for all purposes, statistical, clinical, and experimental.

Underlying much of the discontent with existing methods is the fact that no matter what terms are used for psychiatric classification, these soon come to be burdened with stigma, and the heat of controversy is a displacement from this difficulty. It would seem more logical to attack the problem of stigma directly than to create or use new names or no names at all. The fate of "Section VIII" of World War II fame is an apt example.

Another displacement of affect may be suspected with respect to the criticism that the classification does not permit a satisfactory classification of observed data, but it would seem that the real problem is not with inability to classify what is known but rather with the fact that not enough is known. The most promising solution, therefore, seems to lie outside rearrangements of classifications of what is known.

On a different level are the criticisms that psychiatric nosology is based on multiple axes of classification and that the percentage of cases found in each

category varies widely without obvious reason from one center to another and from time to time in any given center. That this is true cannot be doubted, but in itself it does not constitute proof that any other method would be better or even less that investigators would be well advised to attempt to operate with no classification whatever.

In many ways the specific criticisms leveled against the A.P.A. classification itself are more important than the more general and theoretical ones because the specific ones are susceptible of more direct corrective action, and a brief critical description of certain specific aspects of the A.P.A. classification is in order.

Acute and chronic brain disorders. This is in many ways the least controversial category. Disorders are grouped under their etiologies, which in turn are arranged in an order standard for all somatic disorders. This is the category that most closely approximates a natural classification, and there is relatively little controversy as to the nosological significance of the associated disorders of memory, judgment, and volition. The material is easily and directly related to the technical literature, and it seems that advances in medical knowledge will be easily accommodated without changing the general structure of the section.

Under this category, there have been some proposals for change, however: (1) It is proposed that the acute and chronic forms should be combined into one list, not divided into independent lists, since the distinction between acute and chronic brain syndromes is often impossible and constitutes a prognosis as to recovery rather than a diagnosis of what is wrong. (2) There is considerable feeling that the names of the disorders here and throughout the classification should be shorn of their polysyllabics, which serve no purpose except to reiterate certain concepts as to etiology and pathogenesis. Such terms as "chronic brain syndrome associated with central nervous system syphilis, meningoencephalitic type" are often cited as being so ponderous that they are never actually used in ordinary communication. (3) The term "brain syndrome" is thought to carry unnecessary connotations and to be insufficiently neutral.

Mental deficiency. The mental deficiency section provides for only two varieties, each being subdivided into mild, moderate, and severe. The intent was apparently to scatter all the organic varieties among the brain syndromes according to etiology, with no provision for other types. This method has proved unsuitable and has led to the creation of a special full length classification for these conditions, which (in outline form) will probably replace the current brevity in the next A.P.A. revision.

Psychotic disorders. These disorders correspond to the functional psychoses of other nosologies, and, although the terminology of the section is different from theirs, the delineation of individual syndromes is basically the same. The general outline of the schizophrenias appears to offer few problems, although other

countries tend to accuse American psychiatry of extending the concept into a pervasive panschizophrenia of classification that has been said to rival the pansexuality of our psychodynamics. The pseudotypes are vigorously questioned, and yet one often hears reference to the pseudoneurotic and pseudopsychopathic varieties in European clinics, and current concepts also envision what amounts to a pseudodeficient type of schizophrenia in children.

There are proposals to simplify schizophrenia by eliminating the acute and chronic undifferentiated, the schizoaffective, and the residual types. There is also a recommendation to drop the term "reaction" throughout the classification as a redundant reiteration of a hypothesis as to causality.

A very important point of difference from European classifications of psychosis is the absence of a category of "reactive psychoses," which is used for situationally induced depressions, paranoid reactions, and excitements. This, to most Americans, seems to be a classification with an unacceptably heterogeneous content.

The differential response of the psychoses to drug therapy has been used both to defend and to attack the idea that functional psychoses are medical entities in any sense. Specific as well as nonspecific reactions can be identified, but in any case the results are on a different level than that applied to the neuroses. To this extent, at least, they seem to constitute a valid category.

Psychophysiologic autonomic and visceral disorders. This group represents a relatively modern nosological concept, but it is now firmly entrenched in European medicine under the name of psychosomatic disorders, the latter term having been first widely accepted in this country. This category appears to be due for little fundamental revision, although there is considerable doubt as to its exact relation to the psychoneuroses and to certain true somatic disorders.

Psychoneurotic disorders. As a group, these are as well recognized as are the functional psychoses, but the delineation of subdivisions is highly uncertain. Mixed syndromes are the rule rather than the exception, and any given case is likely to exhibit different types of disorders at different times. Psychodynamics predominate in the classification and in the treatment of these cases. If one can speak of a "therapeutic specificity," it lies in the fact that somatic therapies, including drugs, play merely a subsidiary and adjuvant role in treatment. The concept of obsessive-compulsive syndrome is perhaps the most stable of the entire group.

Personality disorders. Here are gathered a highly heterogeneous collection of problems in which the conduct disorder tends to dominate and to divert attention from the underlying psychiatric problem. A strong condemnation and social stigma are attached to many of these conditions (drug addiction, alcoholism, and homosexuality), and legal sanctions are

often involved. As a result, the way in which these disorders are grouped gives rise to practical medico-legal problems, and it is quite likely that the current A.P.A. over-all designation of "sociopathic" for all these types may be dropped, since they have nothing in common except the legal attitude toward them.

In addition, it appears likely that the distinction between "personality pattern disturbance" and "personality trait disturbance" may be dropped and that this part of the classification will be simplified.

The current inclusion of special symptom reactions here is highly debatable, and it seems quite likely that this will be radically changed in classifications now being considered for child psychiatry, although the nosology for this group of disorders presents very complex problems.

Transient situational personality disorders. Many of these terms also find their chief use in the psychiatry of children and adolescents, and their revision is under discussion. An essential characteristic of the transient situational disorders, as the title indicates, should be the favorable prognosis as well as the absence of symptoms of well recognized forms of major disorders. Many of the cases remain ill for years, however, and the outcome is not always as favorable as the title indicates. In spite of these and other deficiencies, it must be admitted that there has not yet been formed a generally accepted substitute.

Items not included. Although it is quite possible to place any type of psychiatric disorder correctly within one of the established A.P.A. categories, there are a number of other designations, generally recognized and widely described in the technical literature, that cut across several recognized A.P.A. categories. One of the best known is that of the "war neuroses," also called the "traumatic neuroses"; "folie à deux" is another syndrome often described; "depersonalization neuroses" and "anxiety psychosis" are less well known. A reasonable and valid conclusion that can be drawn from studying such material is that the proved usefulness of the A.P.A. classification within its field does not preclude the finding of valuable information under other headings and along axes that this classification does not recognize. The psychodynamic nosology of Freud is the most outstanding example, but there are others.

Synopsis of current version of A.P.A. Diagnostic and Statistical Manual. Satisfactory use of the American Psychiatric Association classification requires a careful reading of the instructions in the *Diagnostic and Statistical Manual* and close attention to the definition of terms found in Sections II and III of the manual. Section IV ("Statistical Reporting") is lengthy and is not of immediate interest to the physician; neither is the tabulating scheme (pages 78 to 86 inclusive). But Appendix C (pages 120 to 128) requires attention because it contains a list of useful supplementary terms.

Perhaps because of its location in the introduction

TABLE I

Diseases of the Psychobiologic Unit^a

DISORDERS CAUSED BY OR ASSOCIATED WITH IMPAIRMENT OF BRAIN TISSUE FUNCTION	
ACUTE BRAIN DISORDERS	
-1 DISORDERS DUE TO OR ASSOCIATED WITH INFECTION	
000-100	Acute brain syndrome associated with intracranial infection. <i>Specify infection</i>
000-100	Acute brain syndrome associated with systemic infection. <i>Specify infection</i>
-3 DISORDERS DUE TO OR ASSOCIATED WITH INTOXICATION	
000-3..	Acute brain syndrome, drug or poison intoxication. <i>Specify drug or poison</i>
000-3312	Acute brain syndrome, alcohol intoxication
000-33122	Acute hallucinosis
000-33123	Delirium tremens
-4 DISORDERS DUE TO OR ASSOCIATED WITH TRAUMA	
000-4..	Acute brain syndrome associated with trauma. <i>Specify trauma</i>
-50 DISORDERS DUE TO OR ASSOCIATED WITH CIRCULATORY DISTURBANCE	
000-5..	Acute brain syndrome associated with circulatory disturbance. <i>Indicate cardiovascular disease at additional diagnosis</i>
-55 DISORDERS DUE TO OR ASSOCIATED WITH DISTURBANCE OF INNERVATION OR OF PSYCHIC CONTROL	
000-550	Acute brain syndrome associated with convulsive disorder. <i>Indicate manifestation by supplementary term</i>
-7 DISORDERS DUE TO OR ASSOCIATED WITH DISTURBANCE OF METABOLISM, GROWTH OR NUTRITION	
000-7..	Acute brain syndrome with metabolic disturbance. <i>Specify</i>
-8 DISORDERS DUE TO OR ASSOCIATED WITH NEW GROWTH	
000-8..	Acute brain syndrome associated with intracranial neoplasm. <i>Specify</i>
-9 DISORDERS DUE TO UNKNOWN OR UNCERTAIN CAUSE	
000-900	Acute brain syndrome with disease of unknown or uncertain cause. <i>Indicate disease as additional diagnosis</i>
-X DISORDERS DUE TO UNKNOWN OR UNCERTAIN CAUSE WITH THE FUNCTIONAL REACTION ALONE MANIFEST	
000-xx0	Acute brain syndrome of unknown cause
CHRONIC BRAIN DISORDERS ^b	
-0 DISORDERS DUE TO PRENATAL (CONSTITUTIONAL) INFLUENCE	
000-0..	Chronic brain syndrome associated with congenital cranial anomaly. <i>Specify anomaly</i>
000-016	Chronic brain syndrome associated with congenital spastic paraplegia
000-071	Chronic brain syndrome associated with Mongolism
000-052	Chronic brain syndrome due to prenatal maternal infectious diseases
-1 DISORDERS DUE TO OR ASSOCIATED WITH INFECTION ^c	
0..-147.0	Chronic brain syndrome associated with central nervous system syphilis. <i>Specify as below</i>
000-147.0	Meningoencephalitic

^a From the American Psychiatric Association. *Diagnostic and Statistical Manual, Mental Disorders*. Washington, 1952. Courtesy American Psychiatric Association.

^b The qualifying phrase "Mental Deficiency" .x4 (mild .x41, moderate .x42, or severe .x43) should be added at the end of the diagnosis in disorders of this group which present mental

TABLE I—Continued

000-147.0	Meningovascular
0y0-147.0	Other central nervous system syphilis
000-1...0	Chronic brain syndrome associated with intracranial infection other than syphilis. <i>Specify infection</i>
-3 DISORDERS ASSOCIATED WITH INTOXICATION	
000-300	Chronic brain syndrome associated with intoxication
000-3..	Chronic brain syndrome, drug or poison intoxication. <i>Specify drug or poison</i>
000-3312	Chronic brain syndrome, alcohol intoxication. <i>Specify reaction .x1, .x2, .x3 when known</i>
-4 DISORDERS ASSOCIATED WITH TRAUMA	
000-050	Chronic brain syndrome associated with birth trauma
000-400	Chronic brain syndrome associated with brain trauma
000-4..	Chronic brain syndrome, brain trauma, gross force. <i>Specify. (Other than operative)</i>
000-415	Chronic brain syndrome following brain operation
000-462	Chronic brain syndrome following electrical brain trauma
000-470	Chronic brain syndrome following irradiational brain trauma
-5 DISORDERS ASSOCIATED WITH CIRCULATORY DISTURBANCES	
000-516	Chronic brain syndrome associated with cerebral arteriosclerosis
000-5..	Chronic brain syndrome associated with circulatory disturbance other than cerebral arteriosclerosis. <i>Specify</i>
-55 DISORDERS ASSOCIATED WITH DISTURBANCES OF INNERVATION OR OF PSYCHIC CONTROL	
000 550	Chronic brain syndrome associated with convulsive disorder
-7 DISORDERS ASSOCIATED WITH DISTURBANCE OF METABOLISM, GROWTH OR NUTRITION	
000-79x	Chronic brain syndrome associated with senile brain disease
000-700	Chronic brain syndrome associated with other disturbance of metabolism, growth or nutrition (includes presenile, glandular, pellagra, familial amaurosis)
-8 DISORDERS ASSOCIATED WITH NEW GROWTH	
000-8..	Chronic brain syndrome associated with intracranial neoplasm. <i>Specify neoplasm</i>
9 DISORDERS ASSOCIATED WITH UNKNOWN OR UNCERTAIN CAUSE	
000-900	Chronic brain syndrome associated with diseases of unknown or uncertain cause (includes multiple sclerosis, Huntington's chorea, Pick's disease and other diseases of a familial or hereditary nature). <i>Indicate disease by additional diagnosis</i>
-X DISORDERS DUE TO UNKNOWN OR UNCERTAIN CAUSE WITH THE FUNCTIONAL REACTION ALONE MANIFEST	
000-xx0	Chronic brain syndrome of unknown cause

deficiency as the major symptom of the disorder. Include intelligence quotient (I. Q.) in the diagnosis.

^c When infection is more important than the reaction or mental deficiency, specify the infection. If both infection and reaction or mental deficiency are important two diagnoses are required.

TABLE I—Continued
MENTAL DEFICIENCY^d

-X	DISORDERS DUE TO UNKNOWN OR UNCERTAIN CAUSE WITH THE FUNCTIONAL REACTION ALONE MANIFEST; HEREDITARY AND FAMILIAL DISEASES OF THIS NATURE
000-x90	Mental deficiency (familial or hereditary)
000-x901	Mild
000-x902	Moderate
000-x903	Severe
-y	DISORDERS DUE TO UNDETERMINED CAUSE
000-y90	Mental deficiency, idiopathic
000-y901	Mild
000-y902	Moderate
000-y903	Severe

DISORDERS OF PSYCHOGENIC ORIGIN OR WITHOUT CLEARLY DEFINED PHYSICAL CAUSE OR STRUCTURAL CHANGE IN THE BRAIN

Psychotic Disorders

-7	DISORDERS DUE TO DISTURBANCE OF METABOLISM, GROWTH, NUTRITION OR ENDOCRINE FUNCTION
000-796	Involitional psychotic reaction
-x	DISORDERS OF PSYCHOGENIC ORIGIN OR WITHOUT CLEARLY DEFINED TANGIBLE CAUSE OR STRUCTURAL CHANGE
000-x10	Affective reactions
000-x11	Manic-depressive reaction, manic type
000-x12	Manic-depressive reaction, depressive type
000-x13	Manic-depressive reaction, other
000-x14	Psychotic depressive reaction
000-x20	Schizophrenic reactions
000-x21	Schizophrenic reaction, simple type
000-x22	Schizophrenic reaction, hebephrenic type
000-x23	Schizophrenic reaction, catatonic type
000-x24	Schizophrenic reaction, paranoid type
000-x25	Schizophrenic reaction, acute undifferentiated type
000-x26	Schizophrenic reaction, chronic, undifferentiated type
000-x27	Schizophrenic reaction, schizoaffective type
000-x28	Schizophrenic reaction, childhood type
000-x29	Schizophrenic reaction, residual type
000-x30	Paranoid reactions
000-x31	Paranoia
000-x32	Paranoid state
000-xy0	Psychotic reaction without clearly defined structural change, other than above

PSYCHOPHYSIOLOGIC AUTONOMIC AND VISCERAL DISORDERS
-55 DISORDERS DUE TO DISTURBANCE OF INNERVATION OR OF PSYCHIC CONTROL^e

001-580	Psychophysiologic skin reaction
002-580	Psychophysiologic musculoskeletal reaction
003-580	Psychophysiologic respiratory reaction
004-580	Psychophysiologic cardiovascular reaction
005-580	Psychophysiologic hemic and lymphatic reaction
006-580	Psychophysiologic gastrointestinal reaction
007-580	Psychophysiologic genitourinary reaction
008-580	Psychophysiologic endocrine reaction
009-580	Psychophysiologic nervous system reaction
00x-580	Psychophysiologic reaction of organs of special sense

^d Include intelligence quotient (I.Q.) in the diagnosis.^e Indicate manifestation by supplementary term in each.

TABLE I—Concluded

PSYCHONEUROTIC DISORDERS

-x	DISORDERS OF PSYCHOGENIC ORIGIN OR WITHOUT CLEARLY DEFINED TANGIBLE CAUSE OR STRUCTURAL CHANGE
000-x00	Psychoneurotic reactions
000-x01	Anxiety reaction
000-x02	Dissociative reaction
000-x03	Conversion reaction
000-x04	Phobic reaction
000-x05	Obsessive-compulsive reaction
000-x06	Depressive reaction
000-x0y	Psychoneurotic reaction, other

PERSONALITY DISORDERS

-x	DISORDERS OF PSYCHOGENIC ORIGIN OR WITHOUT CLEARLY DEFINED TANGIBLE CAUSE OR STRUCTURAL CHANGE
000-x40	Personality pattern disturbance
000-x41	Inadequate personality
000-x42	Schizoid personality
000-x43	Cyclothymic personality
000-x44	Paranoid personality
000-x50	Personality trait disturbance
000-x51	Emotionally unstable personality
000-x52	Passive-aggressive personality
000-x53	Compulsive personality
000-x5y	Personality trait disturbance, other
000-x60	Sociopathic personality disturbance
000-x61	Antisocial reaction
000-x62	Dyssocial reaction
000-x63	Sexual deviation. <i>Specify supplementary term</i>
000-x64	Addiction
000-x641	Alcoholism
000-x642	Drug addiction
000-x70	Special symptom reactions
000-x71	Learning disturbance
000-x72	Speech disturbance
000-x73	Enuresis
000-x74	Somnambulism
000-x7y	Other

TRANSIENT SITUATIONAL PERSONALITY DISORDERS

000-x80	Transient situational personality disturbance
000-x81	Gross stress reaction
000-x82	Adult situational reaction
000-x83	Adjustment reaction of infancy
000-x84	Adjustment reaction of childhood
000-x841	Habit disturbance
000-x842	Conduct disturbance
000-x843	Neurotic traits
000-x85	Adjustment reaction of adolescence
000-x86	Adjustment reaction of late life

QUALIFYING PHRASES^f

.x1	With psychotic reaction
.x2	With neurotic reaction
.x3	With behavioral reaction

^f The qualifying phrases may be added to any diagnosis in the Psychobiologic Unit when needed to further define or describe the clinical picture. They are not used where such use is redundant.

(page 1), the description of the use of the important qualifying phrases is often omitted in studying the manual. These modifiers create additional flexibility, making it possible, for example, to diagnose chronic brain disorder with psychotic or neurotic or behavioral reaction. In addition, on page 10 further qualifying phrases are provided for mental deficiency of various degrees, making it possible to diagnose chronic brain syndrome of many types with mental deficiency of different degrees.

Section III B (beginning on page 46) shows that the original intention was to include such factors as premorbid personality and degree of psychiatric impairment in the classification, but, so far, this is one of many potentialities in the A.P.A. classification that have been utilized little or not at all. This and other experiences with the manual indicate that, in the field, under actual working conditions, only the relatively simple aspects of a classification tend to come into general use.

Table I is a list of terms in the A.P.A. classification.

naming, at best, one or another truth regarding the subject and often ignoring or obscuring others. Diagnostic categories are man-made orderings, useful if they point to significant variables, obfuscating if some spurious or irrelevant order is suggested.

In attempting to utilize diagnostic labels for human beings, one confronts another problem. Jung put it this way, "Even if everyone knows how everything in a given person has come about, that person would still be only half-understood." In the same spirit, May commented: "We may know a great deal about a patient from his case record, let us say, and may have a fairly good idea of how other interviewers have described him. But when the patient himself steps in, we often have a sudden, sometimes powerful experience of here-is-a-new-person, an experience that normally carries with it an element of surprise, not in the sense of perplexity or bewilderment but in its etymological sense of being 'taken from above.' This is, of course, in no sense a criticism of one's colleagues' reports. . . . The data we learned about the patient may have been accurate and well-worth learning. But the point rather is that the grasping of the being of the other person occurs on a quite different level from our knowledge of specific things about him."

At the same time, however, a 3,000-year record of attempts to categorize mental disorders attests the need for some standards of classification. Certainly, in every other area of medicine, meaningful diagnosis and effective remedy have proven inseparable. The task then is to find a variety of psychiatric nosology that tells more truths about a patient than it implies things that are not true.

Diagnostic categorizations of mental disorder have usually separated conditions with known gross organic precipitants from those that seem rooted in psychological or some subtle, as yet undiagnosable, organic cause. A second variable ordinarily included in diagnostic classification has been an assessment of the seriousness or the magnitude of disruption produced in the life of the person by the disorder. Finally, and especially in recent years, most efforts at the categorization of mental disorder have emphasized the adaptational, the dynamic, the changing and the integrating functions of personality demonstrated as a given individual deals with the opportunities and frustrations of his life.

Neurosis

The term "neurosis" has had differing connotations over the years. At one time, it implied a very severe mental disorder; but at the present time, it suggests a less serious syndrome with a mild to mildly moderate level of psychological pain, anxiety, hyperalertness, and/or withdrawal. The term implies a kind of maladaptation that restricts to some extent the individual's over-all judgment, his ability to make good contact with reality, and his capacity to relate effectively with others in the environment.

14.2 NEUROSIS, PSYCHOSIS, AND THE BORDERLINE STATES

MILTON H. MILLER, M.D.

For many years, two standard questions in medical school examinations have been, "Differentiate between psychosis and neurosis" and "Discuss the borderline psychotic states." However, the usefulness of these diagnostic concepts has become increasingly suspect in recent decades. Menninger states, "These old names are wrong labels and have wrong implications. They have become obsolete and hence dangerous." And, indeed, no diagnostic categorization can be expected to be more than a partial approximation,

In the phenomenological sense, the neurotic diagnosis implies that the individual's world of experience is one in which much anxiety and psychological pain will be encountered unless careful precautionary steps are taken. These precautionary steps may be in the nature of avoidance mechanisms or some form of denial or substitution, usually with an accompanying level of discomfort. A diagnosis of neurosis suggests a kind of person who is fundamentally mistrustful of his own general level of competence and basic merit and of the basic friendliness and accepting nature of the environment. Thus the psychoneurotic individual is conceived of as an individual who lives in a world in which there is real and immediate danger of encountering painful anxiety and/or humiliating self-doubt. He must thus direct an inordinate part of his activities in such a way as to avoid these dangers. As a consequence, he may deny himself the hearty and spontaneous experience of life events and may complain that he is missing many of the good things life has to offer.

In the current American Psychiatric Association classification of mental disorders, a number of psychoneurotic reactions are listed, each naming one predominant kind of defensive pattern operative in the general framework just described. The subdivisions include anxiety reaction, dissociative reaction, conversion reaction, phobic reaction, obsessive-compulsive reaction, depressive reaction (mild to moderate), and psychoneurotic reaction.

Psychosis

Contrasting terms to neurosis have been *normality* and *psychosis*. The latter term has been reserved ordinarily for mental disorders characterized by pervasive and profound alterations of mood, disorganization of thinking, and an associated withdrawal from the real world into a world of highly personalized preoccupations. Menninger has enumerated five classical syndromes that accompany the majority of psychotic patterns: "(1) Pervasive feelings of sadness, guilt, despondence, and hopelessness, with convictions of inadequacy, incompetence, unworthiness, or wickedness; (2) more or less continuous erratic, disorganized excitement, accompanied by a corresponding excess of verbal and motor production and emotional heightening, elation, excitement, irritability, etc.; (3) autistic regression and self-absorption, silliness, mannerisms of speech and behavior, bizarre delusional ideation, irrelevancy and incoherence of speech, posturing, and gross (apparent) indifference to social expectations; (4) delusional preoccupation with one or several themes, usually persecutory in trend and usually accompanied by defensiveness, resentment, suspiciousness, grandiosity, condescension, irritability, etc.; (5) confused, delirious states with disorientation, bewilderment, amnesia, confabulation, and sometimes hallucinations and hyperactivity."

All these symptoms are to be viewed in the context

of active adaptations of personality in the face of disorganizing threat.

Shifting Patterns of Neurosis and Psychosis

Ordinarily, in thinking of the circumstances leading to the emergence of psychosis, an image of mounting anxiety and progressively more disabling symptomatology comes to mind. However, all combinations and permutations of symptomatology are seen in clinical experience. Thus, one encounters individuals with neurotic symptoms who are somehow unable to work or relate effectively and whose over-all life patterns are very disrupted. At the other end of the continuum, one not infrequently sees overtly psychotic individuals with delusions, hallucinations, or disorganized symptomatic patterns and profound periods of anxiety who are, nevertheless, highly successful and creative people. This is, of course, not the rule but tends to be the exception.

The same is true of anxiety. On occasion, one sees extremely severe, disabling, sustained anxiety in neurotic patients and, at the other extreme, individuals who develop pervasive psychotic symptomatology with little or no evidence of accompanying anxiety or stress.

Joan was one of monozygotic twins born to a South Dakota middle class family. She was the more passive of the two girls in personality structure but adjusted well within the family unit, school, and community to all outward appearances until she left home and went to college. At that time, the family decision was to split up the twin girls. Joan went west to a California college, and her sister went east.

Within a few days after arriving at college, Joan became extremely homesick, began to cry uncontrollably, and experienced the first gross anxiety of her life. She sought medical help at the school infirmary because she feared she was having a heart attack. She weathered this crisis and, 10 days after arriving on the campus, met Bob. Within 2 weeks, she had become his steady. Theirs was an idyllic 4-year college romance. All other friends, teachers, learning experiences, etc., were subsidiary to this relationship. They ate most of their meals together, took many classes in common, and were, in a sense, not only sweethearts and lovers but best friends.

They were married 1 week following graduation and moved to a small suburban community in Pennsylvania. Two children were born during the first 4 years of their married life. They remained devoted to each other, yet each was successful in his own respective areas of community activity and family life.

In 1950, unexpectedly, Bob was called to active duty as a pilot during the Korean War. Joan was very shaken and, during the weeks before his departure, cried a great deal, experienced much anxiety, but finally pulled herself together and bravely bid her husband farewell.

Within a few days after his departure, however, Joan began to experience extreme anxiety and tearfulness. In an effort to retain her self-control, she composed a schedule of projects for herself, including a 3-month project of refinishing furniture in the home, a several-month project of sewing for the children, and a project of sewing new clothes for herself in anticipation of her husband's arrival home. She threw herself tirelessly into the furniture-sanding project, using all her spare time and working late into the evening in this effort.

About 2 months after Bob's departure, she became concerned about heart palpitations and entered the local hos-

pital for a 3-day period of tests and examinations. The results of the hospital examinations were "essentially negative," and she was placed on mild sedatives. Her apprehension continued, however, and she began to supplement the sedatives with alcohol. She was particularly agitated during the late evening hours, and her sleeping patterns were disrupted by early morning awakening, bad dreams, and preoccupation with night noises in the house.

Four months after her husband's departure, she precipitously took her children back to the family home in South Dakota and remained with her family for a month. She then returned to Pennsylvania with the children, despite the objections of her parents, who were very concerned over her restlessness. The next several months saw a steady increase in the level of her agitation, attested to by a number of contacts with her physician, two late evening calls to the police department because she felt the house was being invaded, a progressive loss of weight, and the total abandonment of her work projects. By the 7th month after her husband's departure, Joan's condition had deteriorated alarmingly. She cried a great deal, was extremely anxious, felt certain that she would die of a heart attack before her husband returned, and at times would sit mutely for hours, giving little attention to her home or children. Her mother was called by the physician, and ultimately she came to help Joan.

Seven and a half months after Bob's departure, efforts were undertaken by the family physician through the American Red Cross to return Bob to his family. Joan handled this newest development in a peculiar way. There was a sudden demonstration of an outward calm. She insisted on completing dental work before her husband's return, explaining to her mother, "I want to be perfect when he comes back." The family dentist told her that five teeth needed filling and was startled when she asked him to remove these teeth. He declined her urgent request, and Joan began a search of the community to find a dentist who would remove all of the "decayed and rotten teeth." She was ultimately successful.

Immediately afterward, she became frantically agitated, alternately fearful and elated, grandiose, and delusional. She stated that she was the Virgin Mary awaiting the return of God. She was floridly psychotic and actively suicidal when her husband returned.

Joan required 2 years of continuous hospitalization, and she continued to receive out-patient psychotherapeutic help for some years after release from the hospital and return to her husband and children.

Joan was, then, within an 8-month period of time in her life, a normal wife and mother, anxious and edgy, obsessively preoccupied, phobic, somatically fixated, dependent on alcohol, suicidally depressed, and, finally, delusional. She was, to all appearances, normal, neurotic, and psychotic within a relatively short interval. Of course, not all neurotic or psychotic patterns are characterized by this level of fluidity and change.

Borderline States

Compounding the effort to describe inclusive categories of neurotic versus psychotic individuals is the clinical picture presented by a large group of patients who have been variously labeled "borderline psychotics," "psychoneurotic schizophrenics," "ambulatory psychotics," etc. The unifying characteristic in such patients, who vary considerably in terms of individual complaints, is the tendency toward the episodic emergence of very profound psychotic behavioral patterns during times of stress, often with relatively prompt restitution of a less disordered neurotic or even normal clinical picture when stress is relieved.

Hoch and Polatin described such patients as suffering pseudoneurotic mental disorders. This has been an appealing concept to many clinicians, since, among other things, it explained why some apparently neurotic patients proved to be quite refractory to the kinds of psychological therapies that ordinarily were useful in treating neurotic patients. Miller has described the special diagnostic problems posed for the family physician by these patients who present fluctuating psychological pictures, pointing out the tendency of doctors to misinterpret bizarre somatic complaints that have emerged in the face of life stress and thus reflect organismic rather than organ disorder. Knight, in 1938, offered a logistic conceptualization to aid in understanding patients who may present rapidly shifting or fluid symptomatology:

"I believe it was Freud who used the metaphor of a retreating army to illuminate the mixed clinical picture of libidinal regression. I should like to borrow the metaphor and elaborate for the purpose of illuminating ego-defensive operations. Various segments or detachments of the retreating army may make a stand and conduct holding or delaying operations at various points where the terrain lends itself to such operations, while the main retreating forces may have retired much further to the rear. The defensive operation of the more forward detachments would, thus, actually protect the bulk of the army from disaster; but these forward detachments may not be able to hold their positions and may have to retreat at any time in the face of superior might. On the other hand, the main army may be able to regroup itself, receive reinforcements, or gain new leadership and recapture its morale. In that event, the forward positions may hold long enough for the main forces to move forward to, or even well beyond, the stubbornly defended outposts."

Maladaptive Life Style

Another rather complex group of patients who do not fit neatly into any neurosis, psychosis, or borderline state diagnostic categories are individuals who have evolved a rather frozen, often relatively anxiety-free, style of life that encompasses maladaptive or even psychotic ways of interrelating with their everyday life in a seemingly conflict-free way.

For example, one encounters the obsessive, excessively serious, humorless, and compulsive child who grows up to be precisely the same kind of adult. Another fixed pattern is that of the chronically depressed, pessimistic individual who seems to discover constant fulfillment of his disappointing expectations. However, these disappointments are not additive in their consequences, and the patient's depression does not mount but sustains the same magnitude over the years. Such individuals are never happy, but only rarely do they become actually suicidal. Similarly, one may observe patients (usually women) whose life style is characterized by a heavy predominance of hysterical features relentlessly sustained from little girlhood into senescence.

Many of these individuals who have developed highly stylized, conflict-free, maladaptive ways of living have proven to be most refractory to efforts to

help them achieve symptomatic relief or modification of behavior patterns.

The Trend in Classifications

The task of delineating diagnostic categories that will serve more to illuminate than to obscure the mental status and life situation of a given individual is by no means a simple one. Certainly, the trend in thinking about psychiatric diagnosis in recent years has been to stress the dynamic and fluctuating patterns rather than the entity itself. Thus, the American Psychiatric Association classification no longer speaks of neurotic and psychotic states but rather of neurotic and psychotic *reactions*.

Menninger, Mayman, and Pruyser in their book, *The Vital Balance*, propose a unified view of mental illness that dispenses with labels and substitutes a method of diagnosis in which all disturbed states are seen as sequential stages in a single and reversible process. They propose five levels of personality disorganization, extending from a first level marked by "slight but definite impairment of smooth adaptive control, a slight but definite disturbance of organization, a slight but definite failure in coping" and extending to a fifth level of disorganization, "an extremity beyond psychosis in the obsolescent sense, the abandonment of the will to live." These authors feel that it is now time to abandon earlier concepts of psychosis, borderline schizophrenias, neurosis, etc., in favor of a definition of personality that emphasizes personality's special role as system regulator and maintainer of organization and homeostasis. They

state: "Threatened disorganization evokes tension which may exceed the powers of the habitual 'normal' coping devices of the organism. Various special devices are called upon in the emergency to maintain the equilibrium, perhaps at a lower level of total functioning, with the best possible facade and with a minimum of discomfort."

This manner of thinking about mental disorder may be more consistent with other medical and biological measures, for example, the functional impairment and capacity scale in heart disease, and may anticipate the nature of psychiatric nomenclature in the future.

Chapter 15

Psychotic Disorders. I: Schizophrenic Reactions

15.1 SCHIZOPHRENIA. I: INTRODUCTION AND HISTORY

HEINZ E. LEHMANN, M.D.

Schizophrenia is generally considered to be the prototype of all functional psychoses, and it has been said that "to know schizophrenia is to know psychiatry."

There are an estimated 320,000 hospitalized schizophrenic patients in the United States today. When undiagnosed, untreated, and ambulatory cases are added to this number, the total rises to nearly 600,000. The odds are one in 100 that an individual will be hospitalized as a schizophrenic patient some time during his life. Every year, between 100,000 and 300,000 new cases of schizophrenia are diagnosed in the United States alone. Schizophrenics now occupy close to two-thirds of our mental hospital beds and more than a quarter of all hospital beds.

There may be some 4,500,000 new cases of schizophrenia in the world every year, and the total world schizophrenic population now numbers about 9,000,000—nearly the equivalent of the entire population of metropolitan New York City.

Hospital records provide evidence that the incidence of schizophrenia in the United States has probably remained unchanged, at least for the past 100 years and possibly throughout our entire history, despite tremendous socioeconomic and population changes. However, a recent study of two sample groups of schizophrenic patients, one hospitalized before and the other after the introduction of pharmacotherapy and active social treatment methods, revealed an increased marriage rate in both groups. This increase was more marked in the second group and greater than that for the general population. There was also an increase in the reproductivity rate, more than three times the increase in the general population. The reproductivity rate of schizophrenics has always been distinctly

lower than that of the general population. It is now approaching the latter, and the selective biological disadvantage that in the past had a restrictive effect on the incidence of schizophrenia in the population seems to be gradually disappearing.

Whether one accepts the genetic or the environmental etiology of schizophrenia, there is little doubt that more children in families with schizophrenic parents will mean a growing incidence of schizophrenia in the future. And the cost of schizophrenia, not only in dollars spent for medical and social services but also in human suffering and productivity loss, is astronomical.

Historical Framework

Early observations. The symptoms of schizophrenia have fascinated physicians and philosophers for thousands of years. As early as 1400 B.C., a Hindu fragment from the Ayur-Veda described a condition, brought on by devils, in which the afflicted is "gluttonous, filthy, walks naked, has lost his memory, and moves about in an uneasy manner."

In the 1st century A.D., the physician Aretaeus of Cappadocia noted the essential qualitative difference between patients suffering from the then traditional catch-all known as "mania" and those whom this gifted observer and clinician described as "stupid, absent, and musing"—possibly equivalent to the modern terminology applied to schizophrenics, whom we now describe as stuporous, preoccupied, and in poor contact with reality.

Aretaeus also observed the deterioration of mental faculties and personality in some of his patients, who may well have been schizophrenics. Such patients, wrote Aretaeus, "fall into such a degree of degradation that, plunged into an absolute fatuousness, they forget themselves, pass the remainder of their lives as brute beasts, and the habits of their bodies lose all human dignity." Similarly, Aretaeus clearly described paranoid syndromes among those whom he called "melancholics," for example, delusions of being poisoned, withdrawal, and preoccupation with religion.

Soranus, in the 2nd century A.D., described delusions of grandeur in patients who "believe themselves to be God" or who "refuse to urinate for fear of causing a new deluge." He also gave careful descriptions of stupor states.

After this early era of detached clinical interest and earnest attempts at treatment, the schizophrenic was cloaked for well over 1,000 years in the shadows of superstition and religious zeal. Countless schizophrenics judged to be possessed by the devil were burned at the stake or condemned and confined by society to jails and the unbelievably gruesome conditions of asylums such as Bedlam in England and Bicêtre in France. During this period the schizophrenic was banished from the public eye and was virtually inaccessible to clinicians or scientists for study.

Treatment. The idea of caring for people with mental disorders, rather than simply keeping them, did not emerge again until the 18th century. Psychology had been left to the philosophers, and the laws of the behavioral sciences had not even been thought of. Physicians were confined to the use of physical and chemical remedies that they knew from empirical application in the treatment of other diseases.

The therapeutic armamentarium of these early physicians was actually restricted for centuries to a few standard procedures, such as blood letting, purging, and the administration of emetics. There existed a fantastic pharmacopoeia, which owed many of its principles to the medieval alchemists.

Convulsions produced by camphor and anesthesia produced by ether were also employed occasionally. Shock treatment in the 18th and 19th centuries consisted of twirling the patient on a stool until he lost consciousness or dropping him through a trap door into an icy lake. This early shock treatment, with its emphasis on producing fear and discomfort in the patient, is directly opposed to modern, physiological shock therapy, where every effort is made to eliminate psychological trauma.

Animal magnetism, or Mesmerism, which became the fashion for a brief period in the late 18th and early 19th centuries, was probably not used frequently for the treatment of psychotics. However, moral treatment, applied widely to hospitalized psychotics in the United States during the middle 19th century, resembled in many aspects today's milieu therapy and other social therapies and was probably an effective therapeutic approach to schizophrenic patients at that time.

With the advent of huge mental hospitals in which a personal approach was impossible, moral treatment and its therapeutic gains were lost. A therapeutic vacuum persisted for half a century until the development in the middle 1930's of Sakel's hypoglycemic coma treatment and Meduna's convulsive therapy.

The neuroleptic drugs in the 1950's brought impor-

tant further gains, particularly in the sustained control of schizophrenic manifestations. And despite Freud's firm belief, shared by most early psychoanalysts, that psychotherapy could not be effective in the treatment of schizophrenia, it has been demonstrated over the past few decades that not only is psychotherapy of schizophrenia feasible and frequently effective but it can also provide vitally important new insights into the complex psychopathology of the schizophrenic patient. Nevertheless, there still is no definitive cure for schizophrenia, and nobody has yet succeeded in isolating its basic causes.

Causes. Over the centuries there have been many theories about the causes of psychotic disorders. Among the earliest were the suggestions that insanity resulted from possession by the devil or evil spirits or indicated punishment by the gods. Physical factors in the form of vapors or pressure on the brain were held responsible by those who later tried to cure these states by venesection and purging.

In the 18th century Georg Stahl introduced the idea of a vital force into the theory of disease. And in the 19th century Heinrich Neumann suggested that insanity was due to a "loosening of the togetherness." These concepts indicated an early awareness of the important role of dynamic factors and interpersonal relationships in psychotic disorders.

In fact, during the 19th century a violent controversy developed between those psychiatrists who, as Griesinger had first emphatically proclaimed, believed that all mental disorders were due to physical brain disease and those who thought they were due to a dynamic, psychological struggle between freedom and obstacles, sin and guilt, and other psychological forces. Heinroth derided his opponents of the somatological school because they looked on the human mind "as a cadaver which one could cut to pieces with a knife, or as a chemical compound which could be broken down into elements, or as a mechanical contraption, the workings of which one could calculate with the help of mathematics."

The factor of heredity as a possible cause of psychosis was also considered by psychiatrists of the early 19th century. Morel describes the case of a psychotic boy whose mother had been insane and whose grandmother had been eccentric, suggesting heredity as a definite etiological factor.

Is all mental disorder constitutional and genetically determined, or is it acquired through traumatic experiences in early childhood? The debate between somatogenic and psychogenic schools of thought on the causes of mental disorder and the nature-nurture controversy still go on today.

Classification and diagnosis. The long search for causes and cures of schizophrenic manifestations was certainly impeded by the fact that what we know now as schizophrenia was not even recognized or described as a disease entity until 1896, when Emil Kraepelin brought together under the name "dementia praecox"

a variety of psychotic syndromes previously believed to represent separate diseases.

Classifications in 18th century. In the 1780's Thomas Arnold had differentiated "ideal and notional insanity" from other types of mental disease. This differentiation may correspond to the modern paranoid subtype of schizophrenia in which delusions prevail, although Arnold may also have been referring to the thought disorder that we today consider to be one of the cardinal symptoms of schizophrenia.

The 18th century German philosopher Immanuel Kant also took an active interest in the methodology and classification of mental disorders and stressed the importance of puberty as a critical period in personality development. This emphasis on puberty, in fact, later led psychiatrists to the term "dementia praecox," which was originally defined as mental deterioration beginning at puberty. Kant also pointed out that in insanity a *sensus communis* is lost and is replaced by a *sensus privatus*—contact with reality versus loss of contact with reality, as we would express it today.

Classifications in 19th century. K. G. Neumann introduced the term "recovery with defect." In France, Esquirol, a pupil of the great reformer Pinel, enriched psychiatric terminology with the introduction of the term "hallucinations," which he defined precisely as it is defined today. He also described a special type of psychosis called "monomania," which seems to have corresponded to a certain form of paranoid or paraphrenic schizophrenia.

The French psychiatrists of the early 1800's were apparently well acquainted with the general picture of schizophrenia, since Pinel and Esquirol have described under different names many cases who must have been schizophrenics. These various clinical observations and methodological clarifications prepared the way for the first major milestones in the development of a unified concept of dementia praecox in the 19th century.

Morel in France, a contemporary of Kraepelin, first introduced the term *démence précoce* in 1856. He applied it to the condition of an adolescent patient, originally bright and active, who gradually became gloomy, silent, and withdrawn. The boy expressed hatred for his father and had thoughts of killing him.

At that time, too, the first methodological distinction was made between the terms "idiocy" and "dementia." The former referred to congenital or very early defects and the latter to acquired or reversible defects.

The French concept of *délires*, meaning delusional states, had in Germany been termed *paranoia*. This term was first used by Vogel in 1764 and later by Heinroth, Zeller, and Ellinger in the early 19th century. Wilhelm Sander in 1868 described paranoid states much as we understand them today, and La-sèque in 1871 published a study on the *délire de persécutions*.

In the middle 19th century there began to crystal-

ize, for the first time in medical history, a distinct interest in the nosology of mental diseases. The controversy that started then—and has by no means been resolved yet—was between a classification according to cause and classification according to symptoms.

Those who subscribed to the classification by symptoms found it easy to make their point that few causes of mental diseases were known and that hypothetical assumptions were no solid foundation for scientific groupings of mental illness. The other side claimed that a good classification of diseases must always be based on etiology. Since this group had to make certain assumptions on the causes of mental illness, they found themselves in the midst of another familiar dilemma: Were all mental disorders due to physical brain disease or to a disturbance of the functional equilibrium?

Heinroth had distinguished 48 separate mental diseases and had brought about considerable confusion as a result. In reaction to this confusion, Heinrich Neumann rejected all classifications and declared in 1860 that psychiatry would not be able to progress until it had decided "to throw overboard the whole business of classifications. . . . There is but one type of mental disturbance, and we call it 'insanity.'"

Kahlbaum, a perceptive psychiatric observer, described a pattern of phenomena characterized by pathologically changed motor tension, to which he gave the name "katatonia" in 1868. Kahlbaum's assistant, Hecker, described the symptomatic picture of hebephrenia and gave it its name in 1870, when he pointed out that this disease occurred mainly in young people or adolescents and usually ended in deterioration.

Kraepelin. The stage was set for a bold consolidation and synthesis of these well established but separately conceived psychiatric syndromes. This could not be done without the most expert and critical judgment that could distinguish between authentic clinical syndromes and spurious groupings or artificial classifications. Such a task would also require much creative insight that would make it possible to choose a number of separate, apparently independent diseases and integrate them into one meaningful whole. Emil Kraepelin had these qualifications and the courage to follow through and defend his synthesis in the face of great opposition by skeptics and conservatives among his colleagues.

At first, Kraepelin thought that dementia praecox was identical with hebephrenia and that catatonia and dementia paranoides were separate diseases. He took this stand in 1887. The 1896 edition of his text book distinguished dementia praecox ending in deterioration from manic-depressive psychosis, which does not end in deterioration. And in 1898 at an historic meeting in Heidelberg, he presented a paper entitled "The Diagnosis and Prognosis of Dementia Praecox." Here he unified all primary and secondary dementias into one mental disease characterized by

the lack of external causes, by its occurrence usually in young, previously healthy individuals, and, most important, by ultimate deterioration.

Most of those present at the meeting, the 29th Congress of Southwestern German Psychiatry, opposed Kraepelin's new concept. They objected, as many modern audiences would undoubtedly do today, to a new classification without any etiological or pathological basis. Nevertheless, today Kraepelin stands unopposed as the founder of the modern system of psychiatric classification.

In distinguishing between dementia praecox and manic-depressive psychosis, Kraepelin focused primarily on the outcome: deterioration versus nondeterioration. This new focus, in contrast to a simple collection of symptoms, constituted a major reform in psychiatric thinking. But Kraepelin himself had pointed out that about 13 per cent of dementia praecox patients recovered without deterioration or major defect. Should these, asked critical psychiatrists throughout the world, be diagnosed as dementia praecox sine dementia?

Kraepelin's description of dementia praecox included not only the prognostic factor of final deterioration but also the observed clinical phenomena, such as hallucinations, delusions, stereotypes, disordered affect, etc. These phenomena were a substantial aid to diagnosis; but to arrive at a definitive diagnosis, the clinician might well have to wait for several years to observe the outcome in dementia and confirm the presumptive diagnostic impression of dementia praecox. This was rather awkward. And what about the 13 per cent who did not deteriorate? Most important, could a psychiatrist really pursue his therapeutic task constructively if he accepted in advance the fatalistic dictum that his patient would ultimately deteriorate?

Bleuler. Eugen Bleuler broke through this impasse with his new conceptualization of the whole problem and the new term "schizophrenia" for dementia praecox. Translated literally, this term means "split-mindedness," and Bleuler saw the splitting of the personality, rather than the outcome, as the central feature of this disease. In his classic monograph, "Dementia Praecox or the Group of Schizophrenias," which appeared in 1911, Bleuler reoriented the basic approach to the dementia praecox problem. He no longer considered incurability and terminal deterioration a necessary feature of schizophrenia. To him, schizophrenia was both a disease entity and a psychopathological reaction. Consequently, he expected some patients to deteriorate and others to recover with or without defect.

Bleuler's fundamental contribution was the introduction of hierarchical ordering of symptoms to replace the mere description of equivalent clinical phenomena. In the new hierarchy, he introduced the idea of primary and secondary symptoms, an idea that was later adopted by a number of psychiatric investigators in Germany, such as Schneider, Gruhle, and Berze,

who have referred to them variously as first order or basic symptoms. To Bleuler, the primary symptoms included disturbances of affect, associations, and volition. But virtually the entire clinical picture that Kraepelin had described as typical of schizophrenic pathology was seen by Bleuler as consisting of secondary symptoms, for example, hallucinations, delusions, negativism, and stupor. Ambivalence and the new, important concept that Bleuler first described and that he named "autism" are particularly important features in his clinical picture of schizophrenia.

Bleuler's original monograph describing the group of schizophrenias is, after more than half a century, still a basic reference because it represents brilliant observations and inspired descriptions by an eminent clinician, who painstakingly collected a tremendous volume of material over many years. Unlike Kraepelin, Bleuler had been influenced by Freud's new dynamic insights, and Bleuler's monograph represents a successful welding of Kraepelin's new discipline of systematic classification of symptoms, Freud's sensitive attention to the dynamic importance of the content of symptoms, and Bleuler's own evaluative idea of a hierarchy of symptoms according to their relative weight in the whole clinical picture of the disease.

Meyer. Adolf Meyer, an American and the founder of the psychobiological school of psychiatry, was the third important figure in the development of the schizophrenia concept. He called it "parergasia," a name that has never been widely accepted, and defined it as a reaction to traumatic life situations, the outcome of a complex habit pattern of nonadaptive responses.

Meyer believed not that schizophrenic behavior was brought about by hidden physical or psychic causes but that it was the natural result of a life history that could be clearly traced to various physical, social, and psychological factors in the individual's past. He never subscribed to Kraepelin's or Bleuler's systems of classification, although he acknowledged Kraepelin's historic achievement as a "stroke of genius."

Nor did Meyer accept Freud's comprehensive theoretical framework. Rather than explaining a patient's symptoms in terms of a certain number of universal psychodynamic principles or diagnosing disorders on the basis of a few general principles of classification, Meyer insisted on the unique, idiosyncratic nature of every patient's psychiatric disorder. Each patient, as Meyer saw him, represented his own research challenge, requiring intensive individual study by the clinician, without easy recourse to traditional theoretical explanations or standard diagnostic labeling procedures.

Current types of schizophrenia. Kraepelin described three basic types of dementia praecox: the catatonic, hebephrenic, and paranoid. Bleuler later added a fourth: simple schizophrenia. These four types are generally accepted today as basic schizophrenic syndromes. Later investigators have added a

number of new subtypes, including schizoaffective and pseudoneurotic schizophrenia and the borderline conditions of latent and ambulatory schizophrenia.

In 1939 Langfeldt introduced the concept of schizophreniform psychoses and proposed an additional distinction between process schizophrenia and schizophrenic reaction. His process form of schizophrenia refers essentially to the old dementia praecox concept and was to be diagnosed in schizophrenic patients where final deterioration had either occurred or was to be expected. The schizophrenic reaction, on the other hand, is characterized by symptoms that appear fairly typical for acute schizophrenia, except for certain factors in the patient's history: (1) His prepsychotic personality was not characteristically schizoid but was fairly well adjusted to work and social situations. (2) His psychotic breakdown occurred in close temporal association with and probably due to a traumatic event in his life situation rather than without any discernible external cause.

Langfeldt's distinction into process and reactive schizophrenia is an attractive device that many clinicians use to make a clinical prognosis, good in the case of schizophrenic reaction, poor in the case of schizophrenic process, and a good deal of research has been focused on an objective separation of these two clinical types, either by means of psychological tests or through some biochemical or other physical factors. However, there still is no decisive evidence to prove that these two types are really of a qualitatively different nature and not simply different degrees of severity on a psychopathological continuum.

Conceptual Frameworks of Schizophrenia

Schizophrenia as seen today has many different facets. The following is a brief outline of five conceptual models that may be considered basic ways of viewing this disease.

Physical-biological models. These models are all oriented toward explaining the manifestations of schizophrenia in terms of its causes.

Historically, the primitive physical factors of heredity and pressure or vapors on the brain were at first considered to be the causes of schizophrenic symptoms. Later, autotoxic factors and gonadal (testicular) insufficiency were discussed as possibilities, as was bacterial infection, for example, a particular form of tuberculosis of the central nervous system.

More recent theories have been focusing on specific toxic factors in the blood, such as a globulin plasma factor; on enzyme abnormalities that may interfere with the normal functioning, production, and degradation of biogenic amines (catecholamines and indolamines); on autoimmune processes attacking the brain; and, again, on heredity. The experimental production of model psychoses through the action of psychotomimetic drugs may also be regarded as an

attempt to simulate possible toxic factors contributing to the appearance of schizophrenic symptoms.

Description-classification models. Oriented primarily toward clinical observation, recording, description, and classification, these models have three main approaches: (1) simple, clinical description of syndromes and reaction patterns, (2) synthesis of nosological entities based on clinical judgment, and (3) computer-derived typology based on factor analysis and cluster analysis of behavioral manifestations.

Psychodynamic-interactions models. These models are primarily oriented toward empathic understanding and theoretical explanations of the observed psychopathology. The explanations are based not on experiments but on concepts and constructs referring mainly to functional intrapersonal dynamics and interpersonal relationships.

Originally, Freud described schizophrenia as a deep disturbance of an individual's object relations, a narcissistic psychosis that precluded psychotherapy because the patient was not capable of an effective transference relationship with the therapist. The different symptomatic manifestations of schizophrenia were explained as an interaction of various defense mechanisms against anxiety arising from early psychic traumas.

Another model in this category postulates that certain stages or positions follow each other in regular sequence during the development of the human infant. These positions, for example, the paranoid or the depressed, determine the infant's basic perspective of the world at each respective stage of psychic development. According to this theory, a paranoid psychosis occurring in adult life may represent a pathological regression to an earlier developmental stage.

The most widely accepted psychodynamic model today stresses the primary importance of deeply disturbed interpersonal relationships. Disturbed family communication and interaction may be the origin of the disorder, and effective psychotherapy requires many modifications of the orthodox analytic procedure because of the unusual intensity and precariousness of the transference relationship.

Phenomenological-existential models. These more recent models aim at understanding a schizophrenic patient's mode of existing in and experiencing his world.

The emphasis in these models is on the immediacy and directness of the patient's lived experiences. These are accepted and appreciated as phenomena in their own right and are analyzed strictly within the limits of their own self-evidence (phenomenological analysis). Every effort is made in such analysis to keep completely free from such traditional, preconceived concepts as subject and object, cause and effect, and mechanism of action.

By accepting the patient's pathological world as being given with irreducible immediacy in all its spatial, temporal, and interpersonal aspects and by not

attempting to explain its special nature, the therapist, it is assumed, will be able to encounter the schizophrenic in his own world, the first condition for eventually leading him out of it.

Conditioning-behavioral models. These models aim at explanations of deviant behavior on the basis of experientially established disturbances of acquired response patterns in primitive signal systems that enable the organism to adapt to changes in the perceived environment through neurophysiological learning.

Pavlov saw in schizophrenia the manifestations of generalized inhibition, which he referred to as a chronic hypnotic state. This hypnotic state, representing pathological fatigue of the higher nervous centers, was in his view the result of ultramaximal stimulation. In a nervous system weakened through hereditary or acquired damage, this produces paradoxical or ultra-paradoxical responses.

Current models of this school of thought consider schizophrenia as a chronic condition of nonadaptive responding due to disturbed reinforcement patterns of early experiences. These maladaptive experience-response-reinforcement contingencies lead to faulty generalizations of responses and in this manner interfere with perceptual and cognitive discrimination. Behavioral therapy based on the principles of operant conditioning and aiming at corrective changes in reinforcement experiences seems to have found a place in the total treatment program for certain schizophrenic patients, notably those who, like autistic children, are extremely restricted in their capacity to communicate at any level.

Current Status

The problem of schizophrenia remains an urgent challenge to the researcher, clinician, and sociologist alike. Today, etiological research is actively exploring four major factors: (1) the genetic, the role of heredity; (2) the biochemical, searching for a toxic factor that may be the result of an innate metabolic error; (3) the psychodynamic, the effects of early psychic trauma; and (4) the social, focusing on the role of a disturbed family structure in the life of a schizophrenic.

The diagnosis of schizophrenia is still by no means a clearly defined procedure. The lack of agreement on objective criteria for this diagnosis today embarrasses psychiatrists throughout the world more than ever before because it seriously hampers epidemiological research and comparison of therapeutic results by different methods and clinicians. A modern development in schizophrenia research is, therefore, a growing preoccupation with the diagnostic problem and the role played by cultural influences, changing clinical fashions, and differing schools of thought in diagnosing schizophrenia. Independently, the search for objec-

tive or at least relatively culture-free diagnostic criteria continues.

The area in which the greatest progress has been made since Kraepelin is the therapeutic management of schizophrenia. Psychiatrists have learned to control quite effectively the acute and often the chronic symptomatic manifestations of schizophrenia. With modern pharmacotherapy it is even possible to maintain many schizophrenic patients symptom-free and to prevent relapses. Yet, despite relative success in the therapeutic control of schizophrenia, the search for a cure goes on and awaits the solution of the etiological riddle.

Suggested Cross References

More detailed information regarding the epidemiology, etiology, clinical manifestations, and various forms of treatment of schizophrenia may be found in the specific sections on these topics in this chapter. Problems regarding nosology, nomenclature, and differentiation between neurosis and psychosis are further discussed by Brill (Section 14.1) and by Miller (Section 14.2), respectively. Further references to the history of schizophrenia may be found in Mora's chapter on the history of psychiatry (Chapter 1). General concepts of the epidemiology of psychiatric disorders are covered by Lemkau and Crocetti (Section 5.1) in Area B, on the basic behavioral sciences.

15.2 SCHIZOPHRENIA. II: EPIDEMIOLOGY

GUIDO M. CROCETTI, B.Sc.

PAUL V. LEMKAU, M.D.

One of the major problems in the application of the epidemiological method to mental illnesses is the definition of a case. The problems of case definition are greatest in those chronic diseases of unknown etiology, of which schizophrenia is a classic example. Here the maximum reliance must be placed on clinical evaluation. In such diseases there are no laboratory procedures to supplement the judgment of the physician.

At first sight, this appears to impair the application of the epidemiological method to the mental illnesses. Admittedly, it does create special problems. However, these problems are logically no different from those that confronted investigators into the epidemiology of many infectious diseases a century ago. Then, too, the specific etiological agents were unknown, as were the modes of transmission and patterns of the diseases involved. In other words, in and of themselves, these limitations do not automatically invalidate the application of epidemiological methods by the investigator of mental diseases.

In the epidemiological investigation of mental illnesses, many types of case definition have been used. Some studies have relied on hospital admissions and discharges; some studies have relied on a physician's examination; some studies have used a physician's examination followed by a psychiatric evaluation of that examination; some studies have used a lay interview, which was then evaluated and scored by a panel of psychiatrists. Several recent studies have used register statistics. This requires an area—usually a state—where every individual making use of either outpatient or in-patient psychiatric services is centrally listed, along with certain information about his age, diagnosis, treatment, etc. Whatever means of case definition is used, it must be the same for all groups involved. The assumption here is that within reasonable limits the errors produced by the type of case definition will be approximately the same among all the groups being studied and compared. Therefore, these errors, if reasonable precautions are taken, will be distributed in an essentially random manner. Thus, although such errors may change the magnitudes involved, they will not in any fundamental sense change the nature of the comparisons. This assumption, of course, does not always hold. If too many false positives or false negatives are included in the group being compared, true differences may well be obscured.

The application of these methods to schizophrenia is beset with difficulties. As a recent comprehensive review by Mishler and Scotch noted, "Like both clinical

and experimental investigations, the epidemiologic study of schizophrenia has had to face serious methodological and conceptual problems that have interfered with the steady growth of empirical information and also of theoretical understanding." However, it is possible to review various epidemiological studies of schizophrenia and to observe the emergence of some broad general outlines and patterns.

Incidence and Prevalence

To begin with, there is the question of the over-all incidence and prevalence of schizophrenia. How important and frequent a disease is it? Lemkau and Crocetti have stated:

When discussing such over-all statistics, several caveats must be borne in mind. Ideally, such statistics are arrived at by selecting a broad sample of the world's population, having each member of the sample diagnostically examined in the same way, and then counting the number of positive and negative cases. Even in such an idealized and oversimplified design, massive conceptual and procedural problems have to be overcome. Obviously, no such ideal study exists.

What does exist are numerous fragmentary studies of limited populations carried out under a variety of conditions and diagnostic procedures, case definitions, etc. Added to these difficulties is the fact that many of these studies were done at different times. In the time between the earliest and latest studies, the diagnostic definition of schizophrenia was itself undergoing considerable change. Furthermore, the overwhelming majority of the studies involved deal with the West European populations. What the investigator does under such circumstances is to attempt a careful analysis of the various studies, try to establish corrective statistics for each study so as to make them all generally comparable, then on this basis formulate a minimal and maximal estimate of prevalence and incidence and select by some criteria the estimate that he feels will have the least chance of containing error.

It is obvious that such estimates are highly subjective statistics. In fact, many medical statisticians will not attempt them at all, since they are bound to be in error. The heavy stress on the limitations of these statistics is necessary since, once formulated and published, they tend to assume a life of their own. They are cited in the literature with decreasing regard to the qualifications that accompanied their original formulation and tend to become fixed and immovable points of reference. In addition, since most of these statistics were based on studies available at a particular time and since new studies are constantly being published, the figures should be continuously reevaluated in the light of new data.

It would seem that the true incidence of schizophrenia in a western European type of society can hardly be less than 50 per 100,000 and within all reasonable probability does not exceed 250 per 100,000 per annum. The incidence range most likely to contain the least error in its general application to various communities in western European type societies is approximately 150 cases per 100,000 population per year. That is to say that the true rate for various communities in these societies can be expected to fall above as well as below this figure with equal frequency.

The above figures allow for both hospitalized and nonhospitalized patients. If case definition is restricted to first admissions to state mental hospitals, the figure for New York State in 1950 was 35 per 100,000, accord-

ing to Kramer et al. If allowance is made for schizophrenic patients in private mental hospitals, in general hospitals, and in ambulatory treatment, it can be seen that the resultant estimated figure must be close to the minimum estimate cited above.

Estimates of the prevalence of schizophrenia—that is, the proportion of a population that would be diagnosed as schizophrenic at any one point in time—are even more subjective than estimates of incidence. This is due primarily to the extreme chronicity of schizophrenia and to diagnostic disagreement as to whether an individual who has had multiple schizophrenic episodes but is in a state of remission at a given point of time should be counted as a schizophrenic or not.

Taking a very narrow basis of case definition, namely, hospitalized schizophrenics, on any given day in the United States, there were 160 schizophrenics per 100,000 population in mental hospitals in 1965. In a recent study in Croatia, Yugoslavia, the average rate of hospitalized schizophrenics over a 5-year period was 142 per 100,000 population. When allowances are made for differences in medical practice, bed-population ratios, etc., the two statistics do not appear very different. When one adds to these minimal estimates, based on diagnosed and hospitalized cases, those estimates of the undiagnosed and unknown schizophrenics in the population, the prevalence figure approximates 290 per 100,000 population.

A certain credibility is lent to this figure by another recent Yugoslav study. In this study 4th year medical students took special lectures in psychiatry, visited hospitals, and had cases demonstrated. Then they interviewed at least one member of every household in a carefully defined village. They asked such questions as: "Has any member of this household ever been in a mental hospital?" "Has any member of this household ever seen Drs. ____ or ____?" (These were the psychiatrists who served the areas.) "Has any member of this household ever had the following symptoms?" (An appropriate list was presented.) The students also examined the medications present in the household, looking for any of the drugs commonly used in controlling psychiatric symptoms. On the basis of this interview, they reported cases as "suspected of mental illness" or "not suspected of mental illness." All suspected cases were then examined by a qualified psychiatrist, and a diagnosis was made. On the basis of this examination, there appeared to be in this small Yugoslav village of about 20,000 a rate of schizophrenia of 329 per 100,000 population. Of the group of schizophrenics diagnosed in this study, three quarters were known to some medical authority as schizophrenic, but only a quarter were known to the local medical authorities as schizophrenic. Approximately 25 per cent of the cases uncovered in this study were previously unknown to any medical authority as schizophrenic.

The life expectancy rate may also be used to estimate the magnitude of schizophrenia. What are the chances that any individual of a given age may be

hospitalized for schizophrenia between birth and age 75? Norris studied this problem and estimated that the figures are between 800 and 1,200 per 100,000.

Mishler and Scotch summarized all these estimates as follows: "The proportion of the population likely to develop schizophrenia during the course of a year is about 0.15 per cent; those hospitalized for schizophrenia for the first time during a year constitute about 0.02 per cent of the population; approximately 0.30 per cent suffer from the illness at any one time; about 1.00 per cent of each age cohort may be expected to fall ill at some point during their lifetime."

When one considers the chronicity of schizophrenia—an average of 4 to 5 months of hospitalization for the first episode, an average of 10 years of hospitalization throughout a lifetime in the United States (at least until recent years)—it is clear that schizophrenia is one of the major diseases of mankind, especially when measured in terms of its capacity to remove individuals from a community.

Factors Affecting Rates

Age. The comparison of rates among different groups in the population also provides some interesting insights into the nature of the disease. The clearest finding that occurs is in terms of age groups most likely to be affected. As dementia praecox, the old name for the disease, implies, schizophrenia is primarily a disease of younger age groups. In both sexes, admission rates for schizophrenia are concentrated in the age range from 20 to 40, with the peak occurring in the age group from 25 to 34 years of age. This finding is consistent with findings in earlier studies as well as with recent national census data. Many of these studies showed that the peak age of hospitalization occurred earlier among males than females.

And the authors have stated: "More than half of the currently hospitalized cases—about 59 per cent—are under 35 years of age. Less than 1 per cent are over 65 years of age."

"Among those patients under 35, schizophrenia accounts for the largest single percentage of admissions to state mental hospitals among each sex and racial group. In New York State the percentage of admissions for this diagnosis approaches 50 per cent [of patients under 35]."

Socioeconomic factors. Perhaps the second most striking differential in rates of schizophrenia among various population groups is that between different socioeconomic groups. The original study on this aspect was done by Faris and Dunham, two sociologists, in Chicago in 1936. These investigators divided the city of Chicago into areas and computed the disease rate for each area as measured by first hospital admissions. The rates they found for schizophrenia in different areas ranged between 100 per 100,000 population and 1,000 per 100,000 population. Further, they found that the areas of high rates could be characterized as areas of high mobility and social disorganization.

Earlier there had been studies by the Norwegian psychiatrist Ødegaard. He compared the rates of first hospital admissions among the Norwegian-born population of Minnesota with the rates of first admissions among the native-born population of Minnesota and the population of Norway. The rates were compared on an age and sex basis. Statistically and methodologically, the study is one of the most thorough ever done in this field. The investigator concluded that there was definitely a higher rate of schizophrenia among those Norwegians who had migrated to Minnesota.

These two studies, taken in conjunction, have led to what are usually termed the drift hypothesis and the origin hypothesis of schizophrenia. Briefly, these two contradictory hypotheses may be stated as follows.

The drift hypothesis holds that the schizophrenic in his preclinical and postclinical state is a highly mobile individual and tends to drift into those social areas where there is the highest social mobility and greatest social disorganization and that this accounts for the higher rates found in these areas.

The origin hypothesis sees, in the higher rates of these most mobile and disorganized areas, etiological factors that create a higher rate of schizophrenia among the inhabitants than is true of stable areas. Neither hypothesis has as yet been conclusively tested.

The notion that there are higher rates of schizophrenia among the lower socioeconomic groups than among the higher has been borne out by hospitalization statistics and other studies. This finding is, however, open to several interpretations. For example, the findings of some investigators indicate that there is a tendency among therapists to see psychosis among working class individuals and neurosis among middle class individuals. Such a tendency would, of course, distort the statistics. As Mishler and Scotch stated:

We believe that at this time no reasonable decision can be made as to the merits of the alternative explanations of the relationships found between social class and the incidence of schizophrenia. Neither can proper weights be assigned to any set of them taken collectively. The higher rates for schizophrenia found among the lowest social class groups in the studies reviewed here may be a function of errors of measurement or may be an artifact. Before attributing an etiological role to social class, these more parsimonious though less elegant interpretations should be ruled out through systematic investigation.

Migration. The initial findings of a relationship between schizophrenia and migration have not been sustained. The original Norwegian investigator, Ødegaard, undertook a study to compare the rates of hospital admission between those who migrated within the boundaries of Norway and those who remained in their own community. He found that the migrants had *lower* rates of hospital admissions than those who remained in their own community. This was also true for schizophrenia.

In 1956 Malzberg and Lee undertook a study of first admissions to New York State mental hospitals from 1939 through 1941. They concluded:

It has been maintained by several investigators that the relationship between dementia praecox and migration is especially close, either because schizophrenics or persons in the 'schizoid' state tend to migrate or because the stresses of migration tend to precipitate schizophrenia. In the present study the relative rates for the foreign-born in comparison with those for total natives were higher for dementia praecox than for total psychoses, especially among whites. For five-year migrants, however, the differentials in regard to dementia praecox were about the same as those for total psychoses, and for whites they were well below those associated with manic-depressive psychoses. It would seem, therefore, that, if there is an especially close relationship between migration and dementia praecox, its effect relative to that of other psychoses is not always manifested immediately after migration.

In a recent study in Yugoslavia two comparable areas were compared, one having rates of mental hospital admission for schizophrenia twice that of the other. Since the high rate area had a high rate of immigration, it was suggested that the migrants might account for the higher rate of schizophrenia. The birthplace of all patients was known, as was the place of residence immediately prior to admission. These were compared. An individual whose place of residence immediately prior to admission was different from his birthplace was arbitrarily defined as a migrant. An individual who was born in the same community from which he had been admitted to the hospital was defined as a nonmigrant. This was, of course, a rough test, since no information was available on any movement that might have occurred between birth and admission. All that could be inferred from the test was that the individual who had been admitted to the hospital from a community different from the one he was born in had definitely moved. The others may have.

The results of this admittedly limited test were somewhat surprising. The highest rates of all were found among those individuals who were definitely established to have resided in the same community from time of birth to time of admission. The next highest rates were among those who had been admitted to the hospital from the same community they had been born in. The lowest rates were among those individuals who had been born in one community but were admitted to the hospital from another. Although certain statistical problems and problems connected with the definition of migration prevent overgeneralization of this finding, it does seem to support those studies cited previously that found a negative correlation between migration and schizophrenia.

Industrialization. One of the most popular beliefs concerning the epidemiology of schizophrenia is the notion that rates of schizophrenia are somehow connected with the increasing rates of industrialization of contemporary societies. A correlate of this idea is the notion that schizophrenia is virtually nonexistent in primitive and agricultural societies.

Studies that attempt to compare the incidence and prevalence of schizophrenia among different cultures rarely employ the same degree of sophisticated methodology in studying a primitive culture as that em-

played in studying western European societies. Differences in case-finding techniques and case definition also enter into the evaluation of findings. There are many descriptions in the literature of psychopathological pictures in other than western European cultures, but most of these are anecdotal descriptions of a single case or of a group of cases with no relation to a standard population. Many are reports of cases which are clearly comparable to schizophrenia as it is known to Western psychiatrists, and, as a generalization, it may be said that psychiatrists trained in Europe and the United States seem to find cases which fit these diagnostic categories in whatever cultures they work. As a symptom picture, the disease appears to occur in every population that has been thoroughly studied, whatever its cultural background.

However, the rate of occurrence is quite another matter. It should be stated at the outset that there is no culture which has been studied as intensively as the western European group. There are a great many unsupported statements in the literature that one or another culture has a higher or lower incidence of schizophrenia. Most of these data are purely impressionistic and are frequently based on one or two equally undependable indicators: the investigator's prejudices regarding the etiology of schizophrenia or the use of inadequately gathered statistics. There is evidence that schizophrenia or schizophrenia-like reactions occur in all known cultures. There is extremely little valid data on the incidence or prevalence of the disease in other than western European types of cultures; within rough limits, rates are similar in all those cultures which have been carefully studied.

Cultural change. Another possible relationship between culture and schizophrenia is that relating to cultural change. The thesis here is that individuals undergoing rapid change from one cultural milieu to another are more likely to develop schizophrenia than individuals remaining within a stable cultural milieu. The literature here is somewhat confused. As Murphy put it, "There are almost as many studies which suggest that social change leads to no increase in mental disorder, or even to a decrease, as there are studies suggesting that an increase is directly traceable to such a cause."

Investigations that have attempted to use measured changes through time in a limited area as a measure of the impact of cultural change on rates of mental illnesses are rare. One of these, by Goldhammer and Marshall, used rates of admission to a variety of mental institutions in Massachusetts between 1840 and 1940 and ingeniously computed age- and sex-specific rates. This is probably the most rigorous and thorough study done on this problem. Those authors concluded that, contrary to popular belief, there had been no long term increase in the last century in the rates of psychoses of early and middle life. This, of course, includes schizophrenia. If this is true for a rapidly changing area in the United States, the supposition is that it is true for currently changing cultures.

Population density. Population density has also been mentioned as a possible etiological factor in schizophrenia. Animal experiments confirm that increased density in an animal population results in more deviant behavior. The earlier studies by Faris and Dunham are suggestive in this regard. A later study by Tsung-yi Lin also offers some confirmation; he found a ratio of 29 to 14 between rates of schizophrenia in densely populated and sparsely populated areas. However, these findings have not been confirmed, and other studies may be considered contradictory.

Specific area. There is an interesting finding in the Yugoslav studies previously cited. This study investigated a century-old clinical belief among Croatian, Austrian, and Italian psychiatrists that a certain area of Croatia had a much higher rate of schizophrenia than other, comparable areas of Croatia. This belief was first tested against unduplicated hospital admission statistics and was confirmed. The usual fallacies attributed to using hospital statistics as a basis of incidence or prevalence—different patterns of diagnosis, different medical care systems, different community resources, etc.—were tested and ruled out as possible contributing factors. The notion was then tested against the statistics of rejection for military service, which in Croatia is independent of local physicians, and again it was confirmed. Next, the populations of a series of communities in two areas—one of them the area in question—were screened by interview and psychiatric examination, and again the hypotheses that the one area had a higher rate of schizophrenia was confirmed. The final step, a screening of a probability sample of the populations in the two areas, has not yet been reported.

The virtually unique finding of this study, as contrasted to others, is that not only does the rate of schizophrenia seem to be significantly higher (by a 2 to 1 factor), but approximately the same difference seems to apply to all psychoses when compared between the two areas. This may—but does not necessarily—support the old belief in a more or less common etiology of all psychoses. There are several alternative explanations. For example, any weakened population or a population having a high prevalence of any given somatic or psychiatric diseases may reasonably be expected to be more vulnerable to any other disease. In other words, there may well be in many populations a nesting of disease, such that increased vulnerability to any one disease increases the vulnerability to any other.

Conclusions

In summary, then, the evidence provided by the epidemiological analysis of schizophrenia, except for over-all prevalence and incidence by age of onset of the disease and its existence in all cultures, is ambiguous and contradictory. However, the differences in rates among different groups uncovered by epidemiological investigation to date strongly suggest that there are

demographic, social, and cultural factors that have powerful selective influences for the individuals who do develop schizophrenia.

Although the general principle of the applicability of the epidemiological method to schizophrenia seems to have been well established by the studies done, their failure to deal with other than macrosociological variables and their failure to assess the relationship of subtypes of schizophrenia to specific demographic, sociological, and cultural variables may have obscured any basic relationships that exist. It may well be, for example, that for a specific subgroup in the population, different types of individuals become more or less schizophrenic than is true in the general population. Present studies do not provide a fine enough sieve to test such a hypothesis.

What conclusions, then, can be drawn about the epidemiology of schizophrenia? First of all, it is a major disease of mankind. Second, it is a disease that finds most of its victims in the younger age groups, those age groups that are in transition between adolescence and maturity. Third, there is some evidence that those who migrate to radically different cultures are more vulnerable. Fourth, there is evidence that those who live in socially disorganized areas are more vulnerable to the disease than those who do not live in such areas. Finally, those populations having the most psychosis also have the most schizophrenia.

Taking all these things into consideration and emphasizing the fact that this final statement is speculation on the basis of inadequate data at hand, schizophrenia seems to be a disease of multiple entities and causes or a disease of high risk for those who are in transition from one social role to another—or both.

15.3 SCHIZOPHRENIA. III: ETIOLOGY

HERBERT WEINER, M.D.

Within the past few years, many theories have been advanced by various disciplines on the etiology of schizophrenia. In fact, however, many of these theories are not empirically based and might more accurately be termed hypotheses or even speculations. Moreover, they do not always distinguish between pathogenesis and etiology, and they may deal with one or the other or both. This section attempts to evaluate, in the light of established findings, current genetic, chemical, physiological, psychological, and sociocultural hypotheses (and speculations) concerning the etiology of schizophrenia as well as those hypotheses that attribute the onset of the syndrome to disturbances in the dynamics of family relationships. In addition, reference is made to the methodological problems in each discipline that impede the testing of hypotheses and the construction of theories.

Problems in the Etiology of Schizophrenia

Definitions. In any discussion of the etiology of schizophrenia, two immediate questions arise: first, what is meant by the term "etiology" in general; and, second, what is meant by schizophrenia? Unfortun-

nately, the first question is the easier one to answer. The second is discussed at length later in this section.

Engel has defined etiological factors as those "which either place a burden on or limit the capacity of systems concerned with growth, development, or adaptation, or factors which, by virtue of their physical or chemical properties, have the capacity to destroy cells or parts of the body."

Interrelationships of factors. In contrast, pathogenesis refers to the course of disease, from its source (in terms of the individual's developmental history) through the sequence of processes and events that lead to its overt manifestations. Pathogenesis would, therefore, encompass predisposing and precipitating etiological factors. A single etiological factor, be it proximate or distal, does not exist in nature. It may be prepotent or predominant, but its complex effects become manifest only through its interaction with other systems. One might speculate, for example, as to the relationship between schizophrenia and a possible aberration in catecholamine metabolism. If this aberration were found to be unique for schizophrenia, could it, in itself, account for the natural history of the disease? Or would such an aberration, provided it existed in combination with other factors—genic, physiological, and social—merely increase the predisposition to schizophrenia? A single etiological factor will not account for all the variance; nor will any invariant combination of causes account for a complex natural process.

In psychiatry, the nature-nurture controversy continues to rage in the guise of claims that either a genic, chemical, or psychological factor can, in itself, provide a sufficient causal explanation of schizophrenia, notwithstanding the fact that every biological organism is conceded to be a product of his genotype as well as his phenotype. The genotype represents a complex organization of potentialities that depend on environmental circumstances for their elicitation. Once these potentialities or characteristics have been elicited, they constitute the phenotype. Concomitantly, psychosocial explanations are neither more nor less biological than chemical ones, in the same sense that developmental, maturational, and ecological processes are just as intrinsic to the study of living organisms and hence to biology as are the chemical constitution or energetics of cells.

Purpose of etiological theories. Discussion of the etiology of schizophrenia is complicated by another major conceptual problem: What are the various etiological theories supposed to explain about schizophrenia?

If schizophrenia is conceived of as a disease modeled after the usual concepts—as a disease, such as a viral infection or a neoplasm, that occurs in persons—then it is entirely relevant to investigate metabolic pathways and to do cytogenetic or cellular biochemical studies. Many have argued, however, that there are only schizophrenic persons, that schizophrenia is not a disease per se. If that is so, then research in

personality development or the testing of personality theories might be more relevant and fruitful. Clearly, such research would be useful at various levels of organization, such as genetic and neurochemical, in the attempt to understand the variables of reaction patterns, rudimentary psychological functioning, and individual differences in these areas. Unfortunately, however, current theories, with very few exceptions, do not attempt to relate one level of organization to another. Genetic theories, for instance, do not usually identify the specific factors believed to be transmitted genetically. Do such theories refer to the thought disorder, to a single symptom or a cluster of symptoms, to prognosis, or to the patient's response to therapy?

The nonspecific nature of these theories seems to prevent their wider application and the construction of an integrated theory of the etiology of schizophrenia. To illustrate, the existential psychiatrists have provided moving descriptions of the schizophrenic patient's empty, meaningless, and lonely existence and of his altered experience of space and time. Certainly, these descriptions are of value inasmuch as they stress the essentially human and personal nature of the schizophrenic experience. However, such experiences cannot be understood as yet in genetic or biochemical terms. Nor has their generality for all schizophrenic patients (and hence their validity as diagnostic criteria) been established.

Diagnosis. Although it has long been a focus for professional concern, diagnosis remains the greatest impediment to investigative work in schizophrenia. In general, it is believed that schizophrenia is easier to diagnose in patients who have been ill for a long time than in patients who are in the acute phase of the illness. Actually, however, reliable diagnostic criteria have not yet been established for either patient category.

Similarly, although there is a growing literature to suggest that the paranoid schizophrenic category may be a distinctive one, on the basis of operational criteria such as responsiveness to drugs and response patterns on various tests, this hypothesis cannot be accepted without serious reservations. It is well known that behavior and symptoms in schizophrenia do not remain stable or fixed; for instance, many paranoid schizophrenic patients were initially characterized by catatonic manifestations.

Experimentation. The problem of diagnosis becomes particularly urgent in relation to the selection of subjects for experiments and in framing hypotheses concerning the etiology of the illness on the basis of such experiments. Once such hypotheses have been formulated, there is no assurance that they derive from observations of a homogeneous population.

More specifically, a review of the history of research in the psychology, psychophysiology, and biochemistry of schizophrenia discloses that investigations in these areas have followed three patterns: (1) Two investigators studying the same or similar func-

tions in different populations of schizophrenic patients either have been unable to confirm each other's findings or have produced two sets of contradictory data. (2) When similar criteria are used in the selection of subjects, different investigators, studying the same functions, have been unable to confirm each other's findings. (3) When normal and schizophrenic subjects are compared for differences in performance or functioning, findings have most frequently stressed the variations within the experimental group. However, the experimental and control groups have not demonstrated distinctive differences in central tendencies. Research workers have learned from such experiences that many experiments require two control groups—a normal one and one drawn from other hospitalized patients.

Differences in sex, socioeconomic status, educational level, intelligence, ethnic origin, premorbid history, length of hospitalization, or diet do not in themselves account for these confounded results; nor can the results be attributed to differences in research goals, methodology, sampling procedures, or the type of tasks involved. Therefore, one may justifiably ask whether the schizophrenic group is, in fact, in any way homogeneous and the disease a unitary one.

On the whole, attempts to use prognosis as a differentiating criterion in the selection of experimental groups and to divide schizophrenic patients into process and reactive groups have not been completely successful. These two ways of categorizing patients have prognostic implications. Prognosis is, however, determined by many social variables as well, such as economic status and education. The original criterion for forming the process and reactive groups was on the basis of how explicit was the disturbance in thought processes.

Single symptoms or clusters of symptoms are not dependent variables on which to base the selection of experimental subjects in view of their changing, labile, and nonspecific nature. However altered psychological functions may be, we do not know as much as we should, perhaps, about the discriminating power of alterations in perception, selective attention, reality testing, thought processes, personal relationships, memory, learning, self-object differentiation, motility, and the control and regulation of behavior, and affects in schizophrenia. Most probably, various combinations of such alterations may form the most reliable diagnostic criteria.

It is proposed that etiological theory must attempt to explain why and how one or another or all of these functions become altered to produce the clinical picture known as a schizophrenic reaction.

Psychological Theories of the Etiology of Schizophrenia

Psychiatric theories. Psychiatric and psychoanalytic observations have contributed richly to the unraveling of the incoherence and incomprehensibility of schizophrenic language, semeiology, and be-

havior. Whereas schizophrenia was once considered a disease of neuropathological etiology with a fixed outcome and schizophrenic patients were considered beyond the pale of humanity, psychiatrists have since learned a great deal about the meaning of bizarre behavior and symptoms and the disturbances of psychological function. They have also learned that schizophrenic patients can be cured. Unfortunately, there has been a tendency to neglect diagnostic criteria and etiological investigations in the heat of therapeutic zeal. The ability to understand the seemingly incomprehensible and idiosyncratic is a major advance, of course. But, such understanding in itself may contribute little to a theory of etiology or even to the patient's progress.

Early psychiatric theories. Bleuler and Freud contributed to our understanding of schizophrenic behavior and symptoms through their efforts to refine descriptions of the cognitive, affective, attitudinal, and behavioral disturbances that characterize the illness. In addition, Freud was interested in establishing causal correlations between certain kinds of unconscious conflicts and certain symptoms, such as delusions and the loss of reality testing. He was also interested in describing the nature of schizophrenic withdrawal and its effect on the patient's relationships with others and on the development of megalomania. He also inferred the existence in some schizophrenic patients of a complex defense structure that leads them to ascribe their own unconscious motives to others.

However, Freud was more interested in the neuroses than in the psychoses, primarily because the psychoses were not considered amenable to psychoanalytic treatment at the time. His contributions to our understanding of schizophrenic phenomena and his views with respect to the etiology and diagnosis of schizophrenia did not differ significantly from those of Bleuler and Kraepelin; therefore, Freud's views in this area are not considered representative of psychoanalytic theory.

Current psychiatric theories. These extend, in one form or another, back to antiquity. Yet, we still do not have conclusive evidence that would enable us to determine which one among them is correct. As a result, the particular theory one ascribes to is a matter of taste, logic, or inclination. Psychiatrists hold theories of the etiology of schizophrenia that range from those that focus on a single cause to those that attribute the onset of schizophrenia to the complex interaction of multiple factors. These theories may be summarized as follows.

1. Schizophrenia is a disease that reflects a material defect in an organ system, perhaps the brain. This defect may be instigated by a hereditary, congenital, metabolic, or structural defect; by an exogenous agent, such as a virus or bacterium; or by an endogenous source, such as the endocrine glands. The onset, course, and prognosis of the disease are, therefore, determined by the inciting cause. The unique psychological and

behavioral manifestations that characterize schizophrenia are epiphenomena of these material defects.

2. Schizophrenia is a physical illness that predisposes its host to limitations in adaptation and thus impairs his capacity to deal with stress. Presumably, the physical disease manifests itself in a deficiency in those psychological functions that are involved in adaptation.

3. Schizophrenic persons are not diseased. For complex reasons, either biological, functional, or social, these individuals are incapable of adapting or are unusually sensitive to certain categories of stress encountered in early adulthood. Predisposition interacts with stress.

4. Schizophrenia is not a unitary disease. Its manifestations are an end product of many possible antecedents, genic, metabolic, physiological, psychological, experiential, and social. In some cases, all these antecedents are present; in others, the presence of only some of these antecedents is sufficient to account for the illness.

5. Schizophrenia is a psychosomatic illness. In the predisposed individual, certain life stresses produce physiological changes, possibly in some major substructure of the nervous system, which, in turn, lower his adaptive capacities and bring about further psychophysiological changes.

6. Schizophrenia is a form of maladaptation originally occasioned by, and appropriate to, the family environment and its interacting members.

7. The schizophrenic person may be described as one whose psychosocial development was arrested early in life, either by severe psychological trauma or by some major deviation(s) in the maturation of his psychological functions. Later, under appropriate intrapsychic or environmentally triggered stress, he is unable to adapt and, instead, returns to levels of functioning that were specific to earlier phases of his development.

Current psychoanalytic theories. In the last 25 years, psychoanalytic observations and hypotheses have focused increasingly on the specification of deviant psychological processes and functions and their manifestations in schizophrenia. In the absence of conclusive evidence, most psychoanalytic theories postulate either a predisposition to vulnerability to stress or a disturbance in the interaction between mother and child or both as the etiological basis for schizophrenia.

Methodological problems. Sophisticated psychoanalytic and psychiatric observations of psychotic persons and the hypotheses engendered thereby are easily criticized for their methodology. First, there is a serious dearth of studies that check inter-rater reliability or deal with attendant problems of observer bias and validation. Second, since many of these studies involve one case or, at best, a few, the generality of hypotheses is questionable. Finally, descriptions of function disturbances are often based on

inferences drawn from the patients' own accounts of their psychological experiences.

It is almost axiomatic that inter-rater reliability is lower for inferences about behavior than it is for behavior itself. Yet the criteria for making inferences can be made operational, and psychological tests do permit validation of clinical impressions of formal disturbances in psychological functioning. Notwithstanding the methodological problems involved, much more clinical research is clearly called for, if only because the psychoanalytic method of single case study enables observation of serial changes in functioning, behavior, and symptoms in a setting designed to permit intensive, long term, focused observation.

Diagnostic criteria. The content of the patient's symptoms, that is, his unconscious motives and conflicts and their transformation into behavior and symptoms, does not play a specific etiological or diagnostic role in schizophrenia, no matter what their therapeutic importance. Hallucinations and delusions, with the possible exception of the primary delusion, are not pathognomonic for schizophrenia. Nor are cannibalistic fantasies pathognomonic for this syndrome, although some would argue that such fantasies represent an etiological factor and are generally present in all schizophrenic patients. Others concede that cannibalistic fantasies lack specificity for schizophrenia but do not dispute their etiological or diagnostic role.

From the psychoanalytic point of view, some distinguishing diagnostic criteria may be found in the formal disturbances in psychological functioning and in their quality. More specifically, the recent focus in psychoanalytic hypotheses has shifted to the ego—the organization of functions that are involved in adaptation and the regulation and control of behavior and that include intellect, language, memory, thinking, perception, attention, intention, reality testing, affectivity, the structure of defenses, object relations, and motility. Genic and biochemical factors are acknowledged but are not deemed appropriate for study by psychological means.

Ego disturbances. On the basis of clinical observation, psychoanalysts have defined and refined the specifics of disturbances in ego organization, both in terms of individual functions and in terms of their interaction. In his pioneer investigations of the psychoses, Federn concluded that a crucial and perhaps fundamental disturbance in schizophrenia was the patient's early inability to achieve self-object differentiation. In the years since, workers have stressed the marked consequences of this defect for cognition and object relations. Bak, Fairbairn, Jacobson, and Mahler, in particular, have emphasized the role of disturbances in object relations in schizophrenia. Beres, among others, has detailed the multiplicity of disturbed ego functions. In contrast, other analysts and analytically oriented psychiatrists have studied those disturbances in ego functioning that give rise to

specific symptoms such as transitive manifestations and hallucinations, and the effects of dedifferentiation of function on the behavior of adult schizophrenic patients.

According to current psychoanalytic opinion, disturbances of ego functions, as well as those of the superego, must be attributed to deviations in their development, maturation, and integration in childhood. These disturbances occur as a consequence of genetic, constitutional factors or as a result of distortions in the reciprocal relationship between the infant and his mother.

Bergman and Escalona have specified one such disturbance that, presumably, illustrates the role of constitutional factors. The infant may be unusually sensitive to the quality and intensity of sensory inputs, which disrupt his behavior. This leads to premature developmental changes to minimize this disruptive effect, which in turn results in the uneven integration of ego functions and his impaired adaptive capacity.

According to this hypothesis, there is a constitutional predisposition to schizophrenia in the form of a defect in rudimentary ego functions or intense hostility and aggression, which produces distortions in the mother-infant relationship, leading to a personality organization that is vulnerable to certain categories of stress. Whether this predisposition is monogenic or polygenic or the result of a biochemical error is not stated. Evidence suggests that a variety of predispositions may be genotypic and that these may lead to the illness by diverse pathways. If the polygenic hypothesis is held, then both the degree of predisposition and the severity of potential stresses should be continuously distributed. However, the differences in clinical subtypes in schizophrenia suggest differences in biological predispositions and concomitantly in psychological organizations, and variations in sensitivity to different stresses.

The etiological significance of disturbances in the mother-child relationship, postulated by proponents of the alternative hypothesis, is most evident in the autistic and symbiotic psychoses of childhood. The autistic child behaves as though animate objects did not exist, and he seems not to be aware of his mother as a separate and distinct person. In contrast, in the symbiotic psychosis, first described by Mahler, the child is unable to progress beyond the closeness and complete dependence that characterized his relationship to his mother in infancy. The illness is characterized by panic when the mother is not present; rage and violent agitation; outbursts of excitement and pleasure, alternating with periods of destructiveness; symptoms that suggest the child is unable to differentiate between self and nonself or to discriminate between animate and inanimate objects; a tendency to confuse inner experience and external events; an overwhelming need to cling to adults; and magical and dereistic thought processes.

Kanner does not believe that genetic or constitutional factors play a role in the autistic psychosis. To support this view, he points to the fact that there is no history of psychosis in the forebears of these children. On the other hand, although Mahler has emphasized the significance of the mother-infant relationship for future development, she contends that some constitutional defect, as yet unspecified, must bear the ultimate responsibility for both forms of childhood psychosis. This is borne out by the available evidence. Although three sets of monozygotic twins have been found concordant for infantile autism, no such concordance has been reported for fraternal twins, despite the fact that fraternal twins are more common than identical twins. Clearly, such reports suggest that genetic factors may play a significant role in the etiology of this form of psychosis.

Some years ago, Mahler suggested that increasing motor coordination, which carries the threat of motor independence, may precipitate the onset of symbiotic psychosis in a child who is so predisposed. More recently, Mahler and Bak have postulated that the vicissitudes of the separation-individuation phase of development, which begins when the child is learning to walk and must separate from the mother and ends with the beginning of individuation, may be particularly crucial for adult schizophrenia. At this stage, the child's pleasure in his newly acquired skills alternates with acute fear of separation from his mother. In the normal course of events, the mother gradually becomes a person in her own right (object constancy), rather than just a provider, and is increasingly perceived by the child as she really is, even as she continues to represent an object of directed feelings and desires. The schizophrenic person never achieved object constancy. When major deviations in this developmental process occur, a number of consequences ensue for other ego functions, which either never differentiate or are poorly integrated or, if they do differentiate, are later subject to dedifferentiation. This is the basis for the disturbances in ego function seen in adult schizophrenia.

The etiological emphasis is on those processes that cause the ego disturbances that later become clinically manifest in the schizophrenic illness. Conflicts and the failure to defend against them or the use of pathological defenses are considered secondary. But why are disturbances in certain ego functions manifest in one schizophrenic patient and not in another? And why does the same patient manifest disturbances in different ego functions at different stages of his illness? The answers are still unknown.

When ego functions are poorly integrated or are not fully differentiated, disturbances in the control and regulation of behavior, personal relationships, and adaptation are evident during the premorbid phase. Characteristically, with the onset of psychosis, further dedifferentiation of ego functions and regressive behavioral phenomena occur. But what causes

this process? There are many hypothetical explanations. Some postulate that this regressive developmental process occurs because of the intense and terrifying hostility and aggression (and their transformation) mobilized at the beginning of the illness in response to a precipitating event. The origins of such hostility and its intensity are not known, but severe deprivation may play a role. Other authors have suggested that there may be some inherent, organismic aspect to this untamed aggression that parallels the inherent disturbances in the rudimentary ego functions. In the course of development, this aggression interacts detrimentally with the maturation and integration of these functions.

Interrelationships of hypotheses. Some of these hypotheses are highly complex, but their behavioral referents are clear. When one is dealing with an organization as highly complex as personality, it is difficult to juggle the interactive forces and, at the same time, keep them all in focus. Again, partly because each author stresses different aspects of schizophrenic phenomenology and symptomatology, the reader may get the impression that various hypotheses are mutually exclusive, when in fact they are not.

Some consensus has been reached that very early in personality development, probably (but not necessarily) as the result of some unspecified genic, polygenic, or congenital influences, serious deviations in the development of higher mental functions occur. Since development is considered to be epigenetic, functions that develop later are, in turn, adversely influenced by these earlier deviations. As a result of these early functional disturbances, the mother-child relationship is also disturbed, with adverse consequences for future development. Thus the pathological developmental process is conceived of as being spiral, and the pathological mother-child relationship is conceived of as neither unidirectional nor bidirectional but as transactional.

One other major problem occurs throughout developmental biology, however. In biology, the magnifying effect of development refers to the observation that the earlier those genes with deleterious effects exert themselves, the more detrimental they are likely to be. But it is not known why some genetic influences do not manifest themselves at birth but do so at a later stage of development. Nor is enough known about the genetics of behavior to determine whether deviations in functioning that occur early in life are genetically or postnatally induced. Clearly, the hypotheses reviewed above require validation, which depends on their translation into testable form, to permit systematic investigation of the variables involved.

Psychological theories. Clinical and experimental psychologists have been involved not only in testing hypotheses derived from clinical observation, but also in developing theories about schizophrenia based on their own work. Many of these theories focus on disturbances of one or another psychological function,

e.g., perception, attention, or learning, in schizophrenia. Others postulate that schizophrenia is a function of a particular kind of social learning process. Thus, the theories advanced by psychologists may be divided into two categories: those that postulate specific deficits in perception and cognition, and those that elaborate on the predisposition-stress concept.

Deficits in psychological functions. In early investigations Kraepelin and Bleuler observed disturbances in attention in schizophrenia. And Jung stated that, to a great extent, formal thought disturbances and symptomatic behavior in schizophrenia could be ascribed to a diminution of attention and apperception. In the years since, many experimental studies of attentional processes in schizophrenia have been performed, but with equivocal results. Most recently, Harway and Salzman have suggested that schizophrenic subjects are more sensitive to external information, whether this leads to accurate perception of the environment or not.

Shakow's extensive studies are especially relevant in this regard. On the basis of reaction time experiments, in particular, he has suggested that schizophrenic subjects tend to be affected or distracted by irrelevant aspects in the context of a stimulus. In consequence, their ability to focus on and attend to the relevant aspects of the stimulus that demands response is impaired. Subjects may also have some difficulty in maintaining a state of readiness for response to a subsequent stimulus and in organizing their response to time. Shakow has described this major cognitive disturbance as "an inability to maintain a major set."

Another important and related theory has been formulated by McReynolds: schizophrenic anxiety occurs because the subject has been flooded by unassimilable percepts. In order to defend against this anxiety, he attempts to integrate and reduce these percepts by apathy and withdrawal. There is a considerable body of evidence to suggest that some schizophrenic patients may at first tend to be overly attentive to many or all stimuli, which are often irrelevant, and later to exclude, reduce, or avoid these stimuli. Again, some schizophrenic patients are excessively attentive and vigilant to stimuli or augment their intensity; other patients do not. Experiments have also demonstrated that there may be an idiosyncratic selection of stimuli that leads to responses to inappropriate stimuli or a greater tendency on the part of schizophrenic subjects to respond to certain classes of stimuli, especially if they are threatening or are otherwise affectively toned.

Although such findings have not yet been linked experimentally to schizophrenic subjects, studies of patients in other diagnostic categories have provided evidence that the focus of attention to stimuli may be narrowed by anxiety arousal. Using the ability to discriminate and the discrimination threshold of two flashes of light separated in time by 5 milliseconds as

a criterion of arousal, Venables found that patients who did not have coherent delusions showed a high correlation between arousal and behavioral withdrawal, the most aroused being the most withdrawn. In another experiment Venables found that the selectivity of attention, measured by the degree to which card sorting on the basis of relevant information was undisturbed by an exchange of irrelevant information, was significantly related to the degree of arousal and withdrawal in chronic nonparanoid patients but not in paranoid subjects. Clearly, such research permits selection of experimental subjects on the basis of validated criteria. In addition, however, it tells a great deal about the interrelationship between different psychophysiological processes, behavior patterns, and cognitive functions in schizophrenia.

Another series of similar studies, carried out by Rodnick and Garnezy, is relevant not only to investigation of perceptual processes in schizophrenia but also to family studies of schizophrenic persons. Their studies imply that the performance of male schizophrenic subjects with a domineering mother and a history of poor premorbid adjustment is affected by conditions of mild censure, especially if the stimulus depicts a censorious mother. Presumably, this complex stimulus induces anxiety aroused by censure, which disrupts performance. However, other investigators deny that censure is selectively or exclusively disruptive, and a third group has concluded that censure actually improves performance, unless censure cannot be avoided by the subject. These studies suggest certain areas for future research; at the same time, they point up some of the difficulties in the control of variables that typically impede such research efforts.

Predisposition and stress. Still another series of theories focuses on both predisposition and learning in schizophrenia. The validation of such theories would require the study of physiological variables, of course. Unfortunately, psychophysiological studies involving schizophrenic subjects have consistently yielded contradictory results. Teams of investigators have variously reported that a group of schizophrenic subjects has a higher resting level of galvanic skin response (GSR) or blood pressure or heart rate. However, one cannot assume, on the basis of such findings, that there is some intrinsic physiological deviation in schizophrenia. The higher resting level may simply reflect the subject's heightened physiological response to the novelty of the experimental situation or to some aspect of the social setting of the experiment or to the experimenter himself. In general, the hypotheses that derive from such studies automatically become suspect, but Mednick's theory merits brief discussion.

Mednick's theoretical proposal, which is based on Hullian learning theory, states that the predisposition to schizophrenia is characterized by excessively strong physiological reactions to mild stress; easy or rapid acquisition of conditioned responses; excessively slow recovery from autonomic imbalance; and excessive

stimulus generalization reactivity. In the acute schizophrenic patient, an increase in anxiety is correlated with an increase in the level and breadth of stimulus generalization. As a result, many new stimuli become potentially capable of arousing anxiety, and a vicious cycle is set up. As generalization widens, atypical and tangential thought sequences intrude, and perceptions are distorted. The chronic schizophrenic state is characterized by learning avoidant and irrelevant thoughts that seek to reduce anxiety whenever it occurs. If these thoughts successfully defend against anxiety, they become self-reinforcing.

It remains to be seen whether studies of physiological responses to conditioning do, in fact, support this hypothesis. With few exceptions, psychophysiological studies have reported lower base levels and autonomic responsivity in chronic schizophrenic subjects. However, Zahn found that in his male chronic schizophrenic subjects, in contrast to a control group, galvanic skin response and heart rate responses, elicited by mild visual and auditory stimuli, were greater and habituated more slowly, despite higher base levels at rest. In addition, when the independent variable was a reaction time situation, physiological reactivity in the experimental group was lower. Thus, Zahn's study supports Mednick's hypothesis in part. However, as is true of all psychophysiological experiments, it is necessary to replicate and validate these findings.

Research studies of segmental set and attention processes, based on Hernández-Peón's work, have led to further hypotheses of a neurophysiological nature. Other neurophysiological hypotheses have also been constructed over the years, ranging from Angyal's contention that the cortex of nonparanoid patients is hyporeactive to more recent speculations that the cortex in such patients is hyperreactive, although neither of these hypotheses clearly specified the neurophysiological significance of such cortical states. Perhaps one can best sum up the efforts in this field by quoting Worden's statement that "there is no neurophysiological contribution to the understanding of schizophrenia."

Finally, Meehl has proposed a predisposition-stress theory that postulates a defect in neural integration as the genotype. Social learning, imposed on this genotype, leads to a type of personality or organization predisposed, but not inevitably prone, to decompensate into schizophrenic illness. This personality organization is characterized by symptoms that closely resemble Bleuler's primary symptoms.

Role of family dynamics and life experience. In the past few years particular emphasis has been placed on the study of the parents and families of schizophrenic patients, with the hope of isolating certain variables, such as some aspects of the behavior, personality, or attitudes of one or both parents, or of specifying modes of family interactions that seem to play an etiological role in schizophrenia. In addition, recent publications have dealt with the relation-

ship between the formal aspects of a parent's cognitive style and the cognitive style of the schizophrenic child.

Methodological and conceptual problems. In this area, as in many other, methodological and conceptual problems abound. Most of these studies are clinical and impressionistic, and rater reliability cannot be assessed. To a great extent, such studies are retrospective and are based on the assumption that current patterns of interaction were also obtained in the past. Validation of findings is not carried out. Bias is introduced by the foreknowledge that a member of the particular family under investigation is schizophrenic or that the parent under study has a schizophrenic child. With few exceptions, no control groups or control individuals are included in these studies, and no attempt is made to find out whether the same or similar parents or families can also be associated with children who are not schizophrenic. Important variables, such as social class, educational level, ethnic and religious origin, are frequently not controlled. Consequently, in family studies especially, nagging questions remain unanswered: Is a schizophrenic child or adult the result of certain modes of family interaction? Is he the cause of that interaction? Is the schizophrenic person involved in a reciprocal relationship with that interaction? Or is he independent of such an interaction?

Characteristics of parents. In studies of parents, the mother has borne the brunt of investigative efforts and, regrettably, the blame. The well documented distortions in the mother's behavior in the reciprocal relationship may, in fact, represent a reaction to the child's behavior rather than its cause. To illustrate, many people who become psychotic in later life are said to have been particularly phlegmatic from a very early age or incapable of responding emotionally, that is, of producing the smiling response. If a mother consistently fails to elicit such a response from her child, she may react with disappointment, exasperation, or whatever. Perhaps it is futile to try to determine whether it is the mother or the infant who must bear the primary responsibility for the distortions in their relationship; it might be more fruitful to study the transaction in greater depth and detail.

Sullivan concluded from his clinical investigations that some of his schizophrenic patients had been rendered anxious as infants by their anxious mothers. Others have described the mother of the potential schizophrenic as aggressive, rejecting, domineering, and insecure, and the father as inadequate, passive, and indifferent. Elsewhere in the literature, these fathers have been depicted as directly threatening, assaultive, or brutal or as overwhelming the child. In contrast to those mothers who are described as either subtly or overtly rejecting, others are said to be fussy and overprotective, perpetuating the symbiotic union. Some mothers are said to assume the role of

the martyr in order to restrict the child's freedom and prevent him from directly expressing hostility.

Several investigators have concluded, on the basis of psychological test findings, that schizophrenic patients perceive either one or both parents as authoritarian. But it is not clear from such studies whether the child's perception of his parent(s) as such is a distortion or whether the parents actually are authoritarian and, therefore, have been perceived accurately.

Alanen, who conducted one of the few studies in which some attempt was made to control for socioeconomic status, age, and residence of members of the experimental and two comparison groups, did find descriptive differences between the mothers of schizophrenic, normal, and neurotic children and adolescents. The mothers of schizophrenic children tended not to understand their child's needs and feelings, were overpossessive and often hostile to their children, and tied their children to them in an inimical bond, although they were unable to be emotionally or physically close to them. Alanen has also suggested that this type of mother treats her child as she herself was once treated by her own mother. Hill and Bowen made a similar observation in their three-generation hypothesis: the grandmother rules the family roost, and the mother of the schizophrenic patient is actually immature but has adopted the domineering manner of her own mother.

The parent-child bond. Another series of studies focuses on the pathological aspects of the close bond that exists between some of these mothers and their children. As mentioned earlier, this closeness, in its extreme form, is clinically manifested in the symbiotic psychosis. Other authors have suggested that the longings and close attachment to the mother characteristic of the normal infant may persist as part of the psychopathology of adult schizophrenic patients. But it is not known whether such longings have a specific etiological significance or appear in response to anxieties of other origins.

The consequence of early deprivation of maternal care, closeness, and need fulfillment have been discussed at length. Presumably, a child who had been raised in a foster home would be exposed to such deprivation. Yet, in a follow-up study of such foster children, Beres and Obers pointed out that, although the great majority (21 out of a total of 38) did manifest some form of personality disturbance, only 4 of the 38 children studied were schizophrenic.

Can these studies provide the basis for a scientific theory of the etiology of schizophrenia? Apparently, these patterns of child-parent interaction lead to a failure or retardation of the child's personality development. This, in turn, leads to a failure of adaptation in late adolescence and early adulthood and thus to schizophrenia. But, once again, it is not known why the failure of adaptation takes this particular form.

Family pathology. The study of the family has as its root the concept that the patient is a symptom of the family pathology and that serious mental disturbances are causally related to mental disease or psychopathology in parents. In other words, the child's present maladaptation was once appropriate to the family environment. For instance, in the extensive series of studies by Lidz et al., the authors described families in which the father courted his daughter to enlist her as an ally in his battle with his wife and to undermine his wife's authority. In another family, the father was ineffective or engaged in direct rivalry with his sons for his wife's attention and care or was a poor and ineffectual model for his sons. Other fathers are described as haughty, aloof, and distant.

The family pathology is conceptualized in such terms as marital schism—that is, a husband and wife stay together despite overt scrapping because one marital partner is dependent on the other—or marital skew—overt harmony masks covert disagreement. Other investigators of family pathology, such as Bowen, speak of emotional divorce to characterize marital partnerships in which there are few overt disagreements but no shared, albeit charged, feelings or in which husband and wife present a compatible facade to the world but cannot tolerate each other in private. When the inadequate member of such a partnership is the wife, she imparts her feelings of inadequacy to the child and is threatened by the child's growing independence.

Wynne has conceptualized the pathology in the family of a schizophrenic child in terms of role theory. He called the relationship pseudomutuality and described schizophrenia as the breakdown of that pseudomutuality. Family members fit together and interrelate according to assigned formal and conforming roles and at the expense of their individual identity and separateness. In schizophrenic families, the number of fixed roles is limited; family members may shift from one role to another within this limited framework. Wynne has also stated that certain specific, formal psychological disturbances, for example, the fragmentation of experience, identity diffusion, disturbed modes of perception and of communication, are a result of the internalization of pathological aspects of the family organization.

Another concept, the "double bind," focuses on certain ways the mother behaves with her child. The child "can't win" in his relationship with his mother. While his father stands helplessly by, the child is made to feel helpless, enraged, fearful, and exasperated, and he deals with his predicament by withdrawing into psychosis.

These conceptualizations and theories overlap. Nevertheless, because so many methodological questions remain unanswered, the data presented have not clearly established an etiological relationship be-

tween family pathology and schizophrenia. In focusing on the early environment of children who later become psychotic, workers in this field have identified certain patterns, but the patterns lack regularity. At best, these studies suggest that the family interaction of schizophrenic persons is disturbed in one way or another. At the same time, from the descriptions of such families it might be concluded that many of the parents were themselves psychotic, so that concomitant association of psychosis in the child might be a function of inheritance rather than a function of family pathology.

Characteristics of the child. As mentioned earlier, investigations of disturbances in the relationship between parent (or family) and child customarily fail to take into consideration the child's contribution to such disturbance. Retrospective studies of schizophrenic adults suggest that there are many roads by which they may have traveled. As children, some showed patterns of clinging to the mother, shared her bedroom until late adolescence, had nightmares, were enuretic, and became fearful and panicky away from home. Others were described as bookish, lonely, friendless, intense, self-conscious, prone to day-dream, seclusive, and oversensitive, with occasional outbursts of temper. A third group was, from an early age, asocial, shameless, and lacking in propriety. The behavior of still another group was overly compliant and conforming; these children were overconcerned with the opinions of peers and parents, prudish, afraid to express themselves, too well mannered, too anxious to please others, inconspicuous, docile, and dull. When such behavioral traits are considered more formally, they may be summarized as reflecting deviations in control and regulatory processes and in relationships to other people and a tendency to resort to day-dreaming.

Predictive studies, such as those conducted by O'Neal, suggest that children who are truants, incorrigible, prone to fight, destructive, irritable, and willful are more likely to develop schizophrenia in later life than are those children who are diagnosed as delinquent or neurotic. Can such childhood behavior and the functional deviations observed be ascribed to family dynamics or to some interactive process between child and mother or to genetic factors? This question cannot be answered on the basis of the available evidence.

Interrelationship of parents and child. In a series of studies (with laudable methodology) recently reported by Wynne and Singer, diagnosis, formal qualities of thought processes, and severity of thought disorganization were blindly and successfully predicted from projective test data obtained from patients and members of their families. The test data obtained on each patient were blindly matched to a statistically significant degree with data from the pa-

tient's family. The conclusions drawn from these studies are appropriately tentative. The findings indicate a close correspondence in family members in the formal aspects of the thought disorder.

Is this formal disturbance learned by the child, or is it inherited? The authors did not commit themselves, but they questioned the assumption made in the family studies reported in the literature that parental influence operates continuously and exclusively in the child's direction. Instead, these authors conceive of the parent-child relationship as a transaction: children bring up their families, as well as vice versa. The structural and formal features of parental behavior and thought undoubtedly influence ontogenesis in the child. But the content of parental attitudes, feelings, and behavior, such as overprotection and domination, may be secondary reactions to disturbances already present in the child.

American theories. For many complex reasons, workers in the United States are particularly apt to produce environmentalist theories that place the burden for the etiology of schizophrenia on the parents and family. Genetic or predisposing factors tend to be overlooked, disregarded, or dismissed as insignificant. Rather, it is stressed that the environment, familial and social, causes certain children to become schizophrenic, and the intervening variables are the categories of life experience that precipitate their schizophrenic reaction. This is the basis for the theory, stated earlier, that schizophrenia is not a disease, that there are only schizophrenic persons, who have been so molded by experience. The behavior of some of the parents of schizophrenic children may differ in intensity from the behavior of parents of nonschizophrenic children but not in quality. Therefore, the mechanisms whereby life experience molds the schizophrenic child are either conflicts created in the child or irrational reactions learned by imitation. The asocial manner of schizophrenic persons is explained by the fact that social learning may also fail in these children because of their pathological environment.

Sociocultural Theories of the Etiology of Schizophrenia

It has already been pointed out that in etiological studies of schizophrenic patients it is necessary to control for a number of variables; among these, socioeconomic status is of major importance. In addition, social factors in schizophrenia are relevant if one is interested in the epidemiology of the disorder, in investigation of the morbidity rates for schizophrenia by social class, in the social mobility of schizophrenic patients, in migration, and in cultural change as important variables in the etiology of the disorder. Sociocultural investigations may also point up the possible etiological role of membership in different ethnic groups or subcultures. If the

incidence of mental illness in two subcultures is found to differ significantly, it may be possible to identify the specific variable(s) responsible for this discrepancy.

However, as a number of experts in these fields have pointed out, the methodological problems inherent in such research are so considerable that no clear answers have been found to any of these problems as yet. As is true in other areas of investigation, the main recurring and confounding problem is the lack of reliable diagnostic criteria. When experimental subjects are not selected on the basis of reliable and comparable diagnostic criteria, the statistics derived from large scale morbidity studies in these areas can only be approximate. In addition, as Lemkau and Crocetti have pointed out, it is necessary to define and enumerate the population from which the sample is drawn and to be familiar with all the known cases of schizophrenia in that population, as well as the estimated ratio between the known and undetected cases.

Social class and mobility. One of the most widely accepted hypotheses about schizophrenia is that it is distributed unevenly among social classes. In order to obtain reliable figures in this connection, epidemiological studies are necessary. However, even if problems of diagnosis and case finding are overcome (which is not always the case), one cannot be certain whether the correlation between illness and social class is not a function of a third variable, such as the rate of remission. Furthermore, the meaning of such results is not always clear, and for the most part the results themselves have led to speculation rather than to further empirical research.

In general, investigations of the relationship of social class to schizophrenia have pursued two main themes: the individual's social status at the time he became ill, and ecological characteristics of his community. The methodology of studies within these two research areas is by no means comparable. Some use occupation as a criterion of social class; others do not. Some control for personal or ethnic variables; others do not. Some study only admissions to state hospitals; other include admissions to general or private hospitals as well. Nevertheless, with the exception of the study conducted by Clausen and Kohn, the findings are usually the same: the highest incidence of schizophrenia, especially in women, occurs in the lowest social class; the lowest incidence is found in the managerial classes. Various interpretations have been attached to these findings, ranging from occupational stress to the low prestige associated with certain occupations. Such factors are thought to precipitate the illness. However, it would be difficult to determine the validity of these findings, particularly since it is often impossible to determine the precipitating event in schizophrenia.

In ecological studies, the highest incidence of schizophrenia is found in the poorest, most disorgan-

ized, and often central sections of the city. In fact, this observation was made originally by Bleuler, who believed such an environment to be the result rather than a cause of the illness. Others, however, believe that such a social environment is in itself responsible for the illness either indirectly by creating conditions, such as social isolation, that favor the onset of schizophrenia in those who are so predisposed or directly by exposing a child raised in such an area to specific types of family constellations, economic deprivation, criminal behavior, or social and group disruption. A third hypothesis states that persons prone to schizophrenia tend to migrate or drift into such areas; and a subhypothesis describes such persons as socially mobile in a downward direction. Still another hypothesis relates these findings to the relative lack of psychiatric treatment facilities, other than hospitals, for members of the lowest classes.

Mishler and Scotch have stated that "at this time no reasonable decision can be made as to the merits of the alternative explanations of the relationships found between social class and the incidence of schizophrenia." And this statement is borne out by studies on the social mobility of persons prone to schizophrenia. Thus the original studies of Faris and Dunham, which related the incidence of schizophrenia to ecological niche, led them to reject the hypothesis of downward social mobility in persons predisposed or prone to schizophrenia. Conversely, others who used control groups in studies of this kind did find some merit in this hypothesis or, at least, trends to support it. However, final validation requires longitudinal studies that control such variables as sex, educational level, and ethnic origin.

Culture change. Schizophrenia has also been linked to such processes as urbanization, industrialization, migration, acculturation, and economic change or crisis. The link between such changes and schizophrenia might be accounted for in two hypotheses: the factor of change may be the direct cause of the illness, or change may be a necessary, if not sufficient, precipitating condition in persons predisposed to the illness.

The effects of migration—or, rather, of emigrant status—have been studied more extensively than any other parameter of social change. Ødegaard's studies in this connection showed that the over-all rate of schizophrenia was higher for emigrant Norwegians in Minnesota than it was for Norwegians in Norway. Malzberg and Lee's studies concluded that schizophrenia is more prevalent among recent immigrants to New York State (both native-born and foreign-born) than it is among persons who were born in New York State. A further breakdown of the migrants studied, according to sex and ethnic origin, indicated that such variables interacted with migration.

But for every study that does find a correlation between migration and schizophrenia, there is one that does not. Nor is it understood precisely how

migration may lead to schizophrenia, if it does. Is migration a consequence of schizophrenia, a precipitating factor, or a direct cause of the illness? And what is the intervening variable? Is it, for instance, separation from others or the isolation and loneliness brought about by migration?

Studies of other aspects of social change are similarly characterized by a lack of comparable findings. For example, one such study has produced the finding that, at least in Massachusetts, there has been no increase in first admissions to state hospitals between 1840 and 1940. The remaining studies, particularly those on acculturation, are impressionistic rather than empirically founded. In brief, one must conclude that the highly complex relationship between culture change and schizophrenia has not yet been demonstrated—if it exists at all.

Cultural setting and clinical subtype. Among the many investigations that have tried to relate sociocultural factors to schizophrenia, the studies of Opler and Singer and of Lambo are of particular interest. These studies have established a relationship between the content of symptoms and ethnic origin. Opler and Singer stated that Irish-American schizophrenic patients accept authority, tend to be paranoid, anxious, and hostile, have inferable latent homosexual conflicts, and tend to resort to alcohol in the face of stress and conflict. Italian-American schizophrenic patients tend to display overt homosexual tendencies, complain about bodily functions, show depressive or elated mood states, or both, and catatonic symptoms and signs. Lambo found differences in the behavior of urban and rural Nigerians who were schizophrenic.

Data concerning relationships between schizophrenic subtypes and membership in a specific subculture are not necessarily of etiological significance, however. In order to establish the etiological significance of such a relationship, it would be necessary to demonstrate that two subcultures studied differed in the incidence of schizophrenia as well. If such a difference were confirmed, it would then be necessary to isolate specific variables prepotent or unique to the subculture with the higher incidence or to some segment within it. No such evidence has been collected as yet; nor is this surprising in view of the fact that an accurate determination of morbidity rates in different subcultures has not yet been achieved. In a broader sense, however, perhaps one of the most serious problems in this, as in many other areas of research in schizophrenia, is what might be called a Rousseauist bias; that is, the underlying concept is that natural man is spoiled, perverted, or rendered ill by his civilized social environment, specifically, that schizophrenia is a disease of civilization. But there is no evidence for this viewpoint.

Genetic Theories of Schizophrenia

The studies on which genetic theories rest fall into two groups: those that deal with the incidence of

schizophrenia in relation to the degree of consanguinity in relatives of known schizophrenic persons, and those that describe concordance rates in twins.

Studies of relatives. Studies in this group report, on the basis of hospital records, that in the general population and in step-siblings the morbid risk for schizophrenia is from 0.9 to 1.8 per cent; in full siblings it is 7 to 15 per cent; for children with one schizophrenic parent, it is 7 to 16 per cent. If both parents are schizophrenic, the risk for the children is between 40 and 68 per cent.

Many workers have criticized these statistics on methodological grounds. First, the diagnosis of schizophrenia is notoriously unreliable and may be too inclusive or exclusive. Second, for various reasons, hospital records are not good sources of data, especially if some of the patients included in the sample under investigation are deceased; in that case, neither the diagnostic criteria nor the reliability of diagnosis can be ascertained. Third, the number of hospitalized cases do not reflect the incidence of a disease but rather its prevalence. Finally, for the most part, the variables of socioeconomic class and environmental factors are not controlled. The significance of such variables is evident in Reisby's findings that the incidence of schizophrenia among children of schizophrenic mothers was 6.8 per cent for inhabitants of rural communities and 14.2 per cent for city dwellers.

Studies of twins. Clearly, the preferred method is the study of concordance rates for schizophrenia in monozygotic and dizygotic twins. These have ranged from 61 to 86 per cent and from 2 to 15 per cent, respectively, in four of the most frequently quoted studies. Kallmann, in particular, has pointed out that the concordance rate differed for monozygotic twins who had not lived together for some years prior to his study (77.6 per cent), as opposed to those twins who had not been separated (91.5 per cent). He also found that many more female than male twins were concordant for schizophrenia, whether they were monozygotic or not.

The studies that produced those statistics have been critically scrutinized on methodological grounds. Rosenthal has pointed out that it is important in concordance studies to evaluate findings correctly. Thus, discordance for a specific clinical picture in twin pairs is likely to be more striking than concordance for a broad diagnostic label. But even the finding that monozygotic twins are concordant for schizophrenia has been disputed by some. The same author has quoted two recent studies of schizophrenia in monozygotic twins carried out in Scandinavia in which two pairs were reported as possibly concordant, as opposed to 22 discordant pairs. Rosenthal has been particularly thoughtful about the possible sources of errors that may lead to an overestimation of genetic factors. At the same time, he has pointed out that there is an almost total absence of schizophrenia in

the families of discordant twin pairs and a 60 per cent incidence in the families of concordant twin pairs. Secondly, the twin in the male discordant pair who does not become ill tends to have the better pre-morbid social and sexual history than his psychotic twin, as judged by the Phillips scale. The discordant twin who does become ill tends to have a better pre-morbid adjustment level than do both members of a twin pair concordant for schizophrenia.

One of the major problems in twin research is that concordance studies are customarily done on hospitalized twins. Admittedly, one wishes to be certain of diagnosis, but it is clearly demonstrable that there is a relationship between high concordance rate and the severity of illness, as adjudged by length of hospitalization. Second, concordance rates in hospitalized twins will be higher if one selects samples from a hospital population rather than from consecutive admissions. However, the twin studies performed by Luxenburger and Essen-Möller are based on consecutive admissions.

The manner in which zygosity is determined is also crucial; many of the classical studies of schizophrenic twins were done before the introduction of modern methods of zygosity determination. When less precise methods are used, there is a greater likelihood that monozygotic twins will be classified as dizygotic. Thus, concordance rates will tend to be higher in monozygotic twins.

In order to establish the reliability and validity of the relationship of zygosity to clinical diagnosis, these two variables should be determined by independent raters, the inter-rater reliability of the dependent variable established, and the variable itself checked for its validity as a criterion. Kety has pointed out that, although concordance rates were slightly lower for both monozygotic and dizygotic twins when the clinical diagnosis was made by hospital personnel rather than the investigator, the difference in concordance rates between the two categories of twins is a striking one nonetheless.

Mode of inheritance. Further discussion of the role of genetic factors in the etiology of schizophrenia has resulted in the formulation of theories of the mode of inheritance, that is, whether the illness is inherited through transmission of a dominant, intermediate, or recessive gene or by polygenic means.

Böök has stated that the schizophrenic psychoses are caused by major genic differences that express themselves in a recessive manner in homozygotes and in a dominant manner in heterozygotes. Because the corrected risk figures for the families of known schizophrenics, that is, for parents, siblings, and children with one or no affected parent, do not differ to a significant degree, a simple recessive mode of inheritance must be ruled out. Böök also postulated a 20 per cent (or incomplete) penetrance in heterozygotes and a 100 per cent penetrance in homozygotes. He has been criticized for the concept of penetrance, but

he has repeatedly stressed that penetrance is an operational and statistical concept. It is, of course, well known that all genes, whether pathological or not, are modified or suppressed by other genes as well as by environmental factors.

Those who subscribe to the theory that the mode of transmission of schizophrenia is polygenic point out that the illness does not conform closely to a Mendelian pattern of transmission, in which event monozygotic twins should be 100 per cent concordant for schizophrenia. However, it should be stated that a polygenic inheritance cannot be established by pedigree methods.

The case against genetic factors. A third group of workers have been particularly vociferous in denying that genetic factors play any role in schizophrenia. And, in fact, provided the figures revealed by twin studies are borne out by further investigations and are not a function of artifacts, it would seem logical to conclude that genetic factors *alone* do not determine schizophrenia. But at this state, it cannot be concluded that they do not play any role at all.

Those who deny the influence of genetic factors point to several pieces of data to support their view. For example, as mentioned earlier, in Kallmann's study more female than male pairs of twins were concordant for schizophrenia. This datum has been explained, however, by the fact that the sample was drawn from a hospital population and by the manner in which zygosity was determined. It has also been postulated that sex linkage, for which there is no evidence, would account for this datum. The lower concordance rate among monozygotic twins who had been separated before they were studied, in contrast to the rate for twins who were not separated, is also quoted in support of the role of nongenetic, environmental factors. The fact remains that one has the impression, even after the most cursory examination of a report such as *The Genain Quadruplets*, that either the family environment or genetic factors would, alone, be sufficient to account for schizophrenic illness in these quadruplets. But there is no offhand way to determine which had greater etiological significance.

Interrelationship of genetic and nongenetic factors. It has been suggested that, rather than plump for nature or nurture, it might be more profitable to identify the genotypically determined traits or deviations in function that are elicited or suppressed by genetic or environmental influences to produce the phenotype schizophrenia. Granting the many difficulties such an investigation would have to overcome, for example, the multiplicity of variables to control and the methodological problems that remain totally unsolved, such research is clearly warranted.

At the same time, one is inclined to feel, after a perusal of the literature, that the psychological makeup of the organism has been neglected in the

argument of how much weight can be attached to genetic or environmental factors. In other words, polemics might well be replaced by the broad principles of modern biology.

The environmentalist school argues that the concordance rates for schizophrenia in twins may be understood either in terms of the psychology of twins or in more complex ways as a result of the way twins are treated by their families. Twins are believed to be vulnerable to special psychological problems: they may be confused in their identity, experience difficulty in self-object differentiation, or be predisposed to homosexual attachment. Methodologically, it would, of course, be possible to eliminate such variables by studying twins who had been separated at birth, with each one raised by a different set of parents. It might be argued that a new set of variables would then be introduced—that of being a step-child or an adopted child—and, of course, this would be so. In the meantime, Rosenthal has pointed out that neither schizophrenia nor any other form of psychiatric illness requiring hospitalization occurs more frequently in twins than in nontwins and that neither occurs significantly more frequently among monozygotic than among dizygotic twins. Is the confusion of identity found in schizophrenia at all the same as that found in twins? If not, clearly it does not play an etiological role in the illness. However, if one ascribes to a multifactor theory of etiology, one might postulate that this factor, in combination with other psychological factors in twin relationships, may play such a role in a genetically predisposed monozygotic twin.

A study of monozygotic twins who had been separated at birth might also yield critical data that would enable one to evaluate the relative influence of genetic and environmental factors in schizophrenia. Such a study would have to take into account the findings previously reported in the literature: In one study, five such pairs of twins were reported concordant for mental illness. In another, no cases of mental illness were found among 63 pairs of monozygotic twins who had been separated at birth. There were some I.Q. differences between the twins in this sample, largely as the result of differences in educational exposure, but there was little difference in personality variables, such as mannerisms, gestures, interests, sociability, and activity. The authors of this study concluded that adverse environmental conditions led to neurotic behavior only when a predisposition was present.

That genetic factors may play a role in personality organization that leads by various routes to schizophrenic illness can hardly be doubted, but the mechanism by which they do so is unknown. It is possible that a genetic factor may operate through a defect in one or another enzyme system, possibly in the central nervous system, which, in turn, seriously alters the psychological functioning, differentiation, maturation,

tion, or development in a manner still to be determined.

The findings reported by Bergman and Escalona, that unusual sensitivities to the quality and quantity of sensory input in infants may predispose to psychosis, suggest that certain kinds of psychophysiological deviations may be traced to a very early stage of development. It is possible that such a deviation could be of genetic origin. Equally provocative is the line of investigation pursued by Bender and Fish. The authors did a follow-up study of infants who, from the age of 1 month, manifested disturbed regulation of physiological patterns (for example, vasomotor instability, poor temperature control, disturbed sleep patterns, poor muscle tone) and uneven patterns of growth with retardation or precocity in motor, perceptual, and language skills and in the social sphere. These children were found to be predisposed to schizophrenia in later childhood. Granted the multiplicity of variables involved in such research and the many technical difficulties, such as the evaluation of the neurological status of an infant, this approach has much to recommend it: the link between genetics and growth patterns or physiological regulatory devices has not yet been established.

Current status of genetic theories. Current genetic theories state that schizophrenia is a specific inherited disease due to a single, mutant, inherited gene that is either recessive, dominant, or intermediate. It is further hypothesized that the genotype is characterized by an undiscovered metabolic error that leads to the schizophrenic illness. The fact that there is less than 100 per cent concordance for schizophrenia in monozygotic twins is explained by a constitutional resistance to the disease. Environmental influences are considered inconsequential. The natural history of the disease—premorbid state, onset, course, remission, and outcome—is either overlooked or is explained in some way by the error in metabolism. Genetic theories account for the variety and instability of clinical subtypes in schizophrenia either by postulating that there is one specific gene for schizophrenia, while other genes modify the phenotype, or by postulating that the subtypes lie outside the sphere of genetic influence. On the other hand, some members of this school believe that schizophrenia is not a single disease but that it consists of several diseases or subtypes, which are caused by different genes.

The specific way the metabolic error manifests itself is not stated with certainty: it may produce either the disease or a predisposition to the disease. This predisposition, in turn, has been variously described as a "characterologic deficit" (Essen-Möller), a thought disorder (McConaghy), a defect in the autonomic system (Mednick), and a defect in neural integration (Meehl). As has been suggested here, it may take the form of defects in a number of integrated psychological functions. It is hoped that future

cytogenetic and biochemical genetic studies will help to dispel some of the ignorance in this field.

Organic Theories of Schizophrenia

One of the etiological theories mentioned above, perhaps the one most stubbornly clung to over time, states that schizophrenia is an organic disease due to a morphological or functional defect in some organ system, perhaps, but not necessarily, the brain. The model is a well known one in medicine: some exogenous agent, infectious or toxic, overcomes the defenses of the body and creates a defect or malfunctioning in an organ or functional unit. Most recently, the endocrine glands have been held responsible for schizophrenia. On the basis of the observation that schizophrenic patients have low stress tolerance, the adrenocortical hormones were investigated and abnormal levels found, only to emerge later as covariants of the patient's behavior. Similarly, when one reviews some of the other findings reported in this area, it becomes obvious that the effects of hospitalization, the lack of adequate controls, and observer bias have been mainly responsible for past reports of chronic bacterial infections of the colon, neuropathological changes in the brain, hepatic disturbances, testicular atrophy, and small hearts in schizophrenic patients.

Recently, the search has been for either an abnormal substance present in body fluids or an aberrant metabolic pathway, both of which are presumably genetic in origin. In other words, schizophrenia is conceived of as an inborn error of metabolism, similar to phenylketonuria perhaps. In this model, schizophrenia emerges as a unitary illness caused by a chemical or metabolic derangement, perhaps of neural functioning. This derangement may reveal itself in the finding of some abnormality of serum or urinary or cerebrospinal constituents. Thus conceptualized, schizophrenia would be analogous to a delirious state (acute brain syndrome) or to some kind of metabolic poisoning.

In the past decade the search for metabolic poisons in schizophrenia has been spurred on by the study of the psychological or behavioral effects of such substances as mescaline, and lysergic acid diethylamide. However, there is good evidence, especially in the European literature, to suggest that the effects of these substances on psychological functioning and behavior are by no means homologous to schizophrenic psychopathology.

Other questions remain unanswered: If such an inborn metabolic error is present, why does it only become manifest in late adolescence or early adulthood, whereas the effects of various amino acidurias or phenylketonuria manifest themselves in childhood? If an abnormal metabolite or an aberrant metabolic pathway does exist, how is one to account for different clinical manifestations and subtypes? How can the premorbid personality or the remissions that occur so

often be explained metabolically? And what accounts for periods of lucidity, both brief or prolonged, when the thought disorder is no longer evident? In fact, such periods of lucidity may occur in response to the physician's attempts to understand or his actual understanding of the patient's seemingly incoherent statements. Finally, if schizophrenia is a chronic delirium, why do fever, surgical operations, and bone fractures produce temporary remissions in some patients? These vexing problems have been studiously avoided by adherents of the organic school. Yet, obviously, etiological statements must take such phenomena into account.

Sources of errors. Despite a marked increase in biochemical and neurochemical research activity in this field, the amount of established, verified factual information accumulated to date is virtually nil. This may be attributed, in large measure, to the fact that no effort has been made to correct several sources of error that in the past have accounted for positive findings. These errors have been both technical and statistical; they have resulted from the tendency to report nonspecific findings; and, in several instances, they arose because of the investigators' failure to take certain crucial variables, involving diet or drug intake, into account.

To illustrate, certain substances may be present in the diet of some patients in a sample but not in the diet of other patients in the sample or in the diet of the control group. Consequently, when these substances are metabolized and excreted, they may give rise to a positive finding. Thus, the presence of phenolic substances in the urine of schizophrenic patients has been traced to their ingestion of coffee, which was not available to the other experimental subjects.

Similarly, the need to control for dietary inadequacies has been underscored by several inaccurate reports of positive findings in the past. Abnormalities in liver function tests, which were postulated as characteristic of schizophrenic patients, were subsequently traced to the low protein diet of such patients and corrected by a high protein, high carbohydrate diet, with added vitamins. Again, the frequently reported finding of depressed thyroid function in schizophrenia has been traced to the low iodine content of the table salt used in hospitals. At present, there is a need to control for adequate vitamin intake in studies that survey the excretion of amino acids by chromatography.

Statistical principles have also been neglected in this area of investigation: if a very large number of substances are sampled by chromatography, some positive results are bound to occur, depending on the level of statistical significance. Furthermore, if one assumes that schizophrenia is not a unitary disease with a stable course and that any group of schizophrenic patients probably represents a heterogeneous population, it may be necessary to compare not only mean values of the experimental and control

data but also the deviance in individual and mean values in each group. Some studies also require observation of variations in individual values over time.

Two of the best known series of studies over the past few years have involved reports of epinephrine and ceruloplasmin that, in all probability, can be understood as a function of low blood levels of ascorbic acid. Originally, these reports claimed an abnormal pathway of epinephrine, with the production of adrenochrome and adrenolutin, which were said to possess psychotomimetic properties. However, the metabolism of isotope-labeled epinephrine does not proceed via these substances in either schizophrenic or normal subjects. Nor could adrenochrome be found in the serum of schizophrenic subjects. At the same time, some reports suggested that epinephrine was metabolized more rapidly *in vitro* after plasma from schizophrenic patients was added. This increased rate of metabolism was thought to be due to elevated levels of ceruloplasmin in such serum. Again, the finding of an increased rate of epinephrine metabolism has since been shown to be a function of low blood levels of ascorbic acid.

Obviously, the finding of an abnormal level of a naturally occurring blood or urine constituent or the presence of an abnormal substance in the blood or urine of schizophrenic subjects does not mean that this phenomenon is specific to schizophrenic illness. For example, in the 1940's some reports appeared in the German literature that serum levels of copper were elevated in schizophrenic subjects, although this finding was not confirmed. However, elevated serum levels of copper are now known to occur in pregnancy and in a wide variety of disease processes, for instance, in chronic infectious diseases, liver disease, malignancies, the collagen diseases, diabetes, adrenal insufficiency, and various blood dyscrasias. Thus, it is crucial in research of this kind to rule out all other disease variables before one can be certain that the elevation of serum copper is a unique characteristic of schizophrenia. Serum copper occurs almost exclusively in the form of the metalloprotein, ceruloplasmin, and in 1957 a rapid test for the presence of ceruloplasmin was developed by Akerfeldt. Shortly thereafter, a number of reports were published that claimed that the test was positive in a large percentage of schizophrenic subjects. Two lines of evidence, however, have since refuted this claim: The confirmed findings of normal levels of ceruloplasmin in schizophrenic subjects, and the finding that a positive Akerfeldt test depends on low blood levels of ascorbic acid. Finally, any abnormal substance found in blood would also have to pass through the blood-brain barrier. Epinephrine, for example, does not do this, according to Weil-Malherbe.

Technical sources of error have probably also accounted for some reports of abnormal levels of constituents of body fluids. For example, Bogoch first

reported that the cerebrospinal fluid of schizophrenic patients contained abnormally low levels of neuraminic acid when boiling whole cerebrospinal fluid with Bial's orcinol reagent. Since this reagent also forms colors with other sugars, one cannot conclude that neuraminic acid alone is being measured. Reports both confirming and refuting Bogoch's findings have appeared. The thiobarbituric acid method to measure the levels of neuraminic acid yields values that are one-third those obtained with Bial's reagent, and these levels are more stable over time. Green et al. have also pointed out the need to control for the age of patients and their control subjects when Bial's reagent is used.

Theories

Genetically inborn error of metabolism. This hypothesis is attractive but has not been confirmed as yet. As concretized by Heath, it links a whole causal chain, beginning with genetic data and proceeding via biochemistry to deviations in psychological functioning, which interact with family and social factors. Each of these processes is a necessary (if not sufficient) condition for onset of the illness. The crucial genetic defect is manifested by the presence of taraxein, which is responsible for an aberration of biogenic amine metabolism.

A variant of this hypothesis is the postulate that epinephrine released by stressful life situations is abnormally metabolized to form hallucinogenic derivatives of epinephrine, adrenochrome, and adrenolutin. However, as noted above, the empirical evidence for this hypothesis has not been verified, and hallucinosis is not pathognomonic for schizophrenia.

Defect in energy metabolism. It has been shown repeatedly that the rates of cerebral circulation and of cerebral oxygen and glucose consumption are normal in schizophrenic patients. Abnormal glucose tolerance curves and the retarded metabolism of lactate, which were frequently reported in schizophrenia in the past, have since been ascribed to a relative deficiency of vitamins of the B group. More recently, defects in oxidative phosphorylation and of the metabolism of phosphorus in erythrocytes have been reported. And schizophrenic patients have been said to own a serum factor producing hyperglycemia, possibly due to an antagonist of insulin present in blood. Finally, in comparison with the plasma of normal control patients, the plasma of schizophrenic subjects is said to contain a substance that, when incubated with chick erythrocytes, increases the lactate-pyruvate ratio in the medium. This finding has not been confirmed by other laboratories; moreover, those who reported it first have since related it to the fact that their subjects engaged in moderate exercise before blood samples were drawn. The mechanism whereby the metabolism of chicken erythrocytes is altered has been worked out recently: human plasma apparently contains an antibody that produces a

complement-linked lysis of chick red cells and an associated stimulation of the cells' aerobic glycolysis. Whether the plasma of schizophrenic patients is unique in containing this antibody remains to be determined; however, there is preliminary evidence that the plasma of nonpsychotic patients may also contain it.

Apart from such considerations, in none of the studies quoted is it quite clear what such findings are supposed to explain about schizophrenia. Are defects in energy metabolism supposed to be etiological of schizophrenia or covariants of the psychological or behavioral state of schizophrenic subjects?

Abnormal serum constituents. The status of work on ceruloplasmin has already been discussed, as has the controversy, which is still unresolved, surrounding the presence and role of taraxein in schizophrenia. Taraxein is said to be related to but qualitatively different from ceruloplasmin. Heath et al. have reported that when taraxein is injected into monkeys, behavioral and electroencephalographic changes occur. And they have linked the taraxein hypothesis to their findings of paroxysmal activity in populations of septal and hippocampal neurons: taraxein is said to impair "enzymatic activity in a pathway related ... to the metabolism of amines," which in turn produce high voltage spike activity in the above-mentioned loci.

There have been reports for many years of the adverse effects of the serum and urine of schizophrenic patients on many dependent variables, for example, cells in tissue culture, tadpole larvae, web construction in spiders, rope-climbing speed and learning and retention in rats, and the pressor response in rabbits following the topical application of epinephrine to the cerebral cortex. The nature of these substances in serum, plasma, or urine has not yet been identified.

Presumably, however, a protein may be responsible for the abnormal antigen in schizophrenic serum, reported by Haddad. Research is underway to determine in what fraction the abnormal protein is found and whether there is a quantitative increase of one or another fraction. Elevations in α_1 -, α_2 -, β -, and γ -globulins have been reported. Another study reports an increase in β -2-macroglobulin in sera drawn from 4 out of 15 schizophrenic patients. Many of these findings lack specificity for schizophrenia, however. For instance, increased globulin levels have been found in delirious states and manic-depressive and puerperal psychoses, and α_2 -globulin elevation was found to be related to agitation, rather than diagnosis. Other investigators have reported that this fraction increases during infectious illness and hypertension, with malignancy, and after trauma.

A form of intoxication. Some psychotomimetic agents, such as mescaline, are methylated congeners of many naturally occurring biogenic amines. Recently, Friedhoff found that the urine of 70 per cent

of his schizophrenic subjects contained the substance 3,4-dimethoxyphenylethylamine, which is related to dihydroxyphenylethylamine (dopamine) and to mescaline (which contains an additional methoxy group). The urine of the normal control group in Friedhoff's studies did not contain this substance, but others have found it in their control groups as well as in their schizophrenic subjects, albeit with less frequency. As Mendelson has pointed out, it has not been possible as yet to determine whether 3,4-dimethoxyphenylethylamine is endogenous rather than exogenous or whether its presence may be correlated with a specific behavioral phenomenon rather than the illness or whether it is capable of producing the characteristic disturbances in psychological function seen in schizophrenia.

That some disturbance in biological transmethylation may occur in schizophrenia is suggested by the research currently underway at the National Institute of Mental Health. Pollin, Cardon, and Kety fed 1-methionine to chronic schizophrenic patients and produced an apparent exacerbation of schizophrenic symptoms. The enzyme *O*-methyltransferase catalyzes the transfer of a methyl group from *S*-adenosylmethionine to dopamine. The source of the methyl group in *S*-adenosylmethionine is 1-methionine. However it is not known whether the exacerbation of symptoms is specific to schizophrenic patients or whether it is due to the nonspecific effects of amino acid intoxication rather than the suspected mechanism.

Deficiency of a central neurohumor. Both Woolley and Gaddum concluded, independently, that a central serotonin deficiency, arising from a metabolic failure, may be responsible for schizophrenia. This hypothesis is based on the fact that lysergic acid diethylamide (LSD) antagonizes the action of serotonin on smooth muscle. Indirect evidence for the hypothesis is the finding that dimethyl serotonin, bufotenin, is a psychotomimetic drug. On the other hand, reserpine lowers the concentration of serotonin in the brain, and the effect of feeding 5-hydroxytryptophan, serotonin's precursor, raises the brain level of serotonin and is said to produce behavioral effects akin to those of LSD. Other contradictory evidence accumulated in this area has been reviewed in detail by Kety.

The hypothesis that schizophrenia is due to a deficiency of serotonin is apparently no longer subscribed to even by Woolley, who reported recently that the blood serum of schizophrenic patients contains a substance, provisionally identified as a ganglioside, with activity as a serotonin receptor, which increases the sensitivity of isolated rat uteri to serotonin. In this manner, the effective concentration of serotonin is increased. It remains to be seen whether this ganglioside is present in the brain of schizophrenic patients. However, this hypothesis is attractive because it shifts attention to the central

nervous system and to a substance with known neurobiological activity.

Alternative theories. Several alternative testable hypotheses might be proposed: for example, certain kinds of ontogenetic experiences might be reflected in altered brain chemistry, which, in turn, might be present locally or be manifested in one or another body fluid. The animal experiments conducted by Krech and Rosenzweig suggest such a possibility. Alternatively, a genetically determined inborn error of metabolism or aberrant metabolic pathway, possibly in the nervous system, might alter the process of personality development in such a manner as to distort or prevent the proper differentiation, integration, maturation, and organization of psychological functions that enable mature adaptation, and, concomitantly, such metabolic errors might alter the processing of real life experiences. There is evidence to suggest that, in a general way, two children may respond to the same experience in quite different ways or to different experiences in the same way. And it is not unusual to find that some adult schizophrenic persons perceive or have perceived the world in idiosyncratic ways.

Obviously, such hypotheses are much too general, in that they fail to specify the possible metabolic error to be investigated. Furthermore, if such an error were identified, one would also wish to understand the mechanism through which it effected changes in psychological processes.

All these hypotheses are plausible. Yet one cannot help wondering how the finding of a specific biochemical substance, for instance, would enhance our understanding of schizophrenia. Presumably, such a substance could be important as a diagnostic aid, that is, as a validating criterion of diagnosis, just as low levels of protein-bound iodine serve as validating diagnostic criteria in myxedema. But such a finding would have no etiological significance per se. Furthermore, a substance or substances might be covariants of some behavioral manifestation. Marked elevations of urinary 17-hydroxycorticosteroid and epinephrine levels were found by Sachar et al. to occur as covariants of acute anxiety and depression in young male schizophrenic subjects. These levels became normal when the patients were independently adjudged to have attained psychotic equilibrium or to have entered a recovery phase.

Future Needs

The main impediment to the formulation of an integrated, coherent theory of the etiology of schizophrenia is the absence of clear cut empirical findings and testable hypotheses. The fact that the proponents of each of the viewpoints reviewed here tend to claim sufficiency and specificity for their particular hypotheses or findings constitutes an additional impediment. This situation is reminiscent of the situation that existed in the field of psychosomatic

medicine some years ago, when specific psychological conflicts or personality types were claimed to be sufficient causes of such diseases as peptic ulcer and essential hypertension. Some clarification was achieved only when Mirsky proposed and proved the hypothesis that neither a specific biochemical or physiological factor nor a specific psychological or social factor was, in itself, sufficient to account for the etiology of peptic ulcer, but that the lesion was the result of the interaction of all three. Such a model might be a useful guide in the search for the etiological factors in schizophrenia and in efforts to account for all the complexity of its natural history. But first, the general principles of biology must be used, linear causal theories must be abandoned, and the interactions and variance in schizophrenia in terms of both heredity and environment must be accounted for. And before that, reliable and valid data on genetic and environmental factors must be collected.

Once this has been done, the nature of the interaction and mechanisms may be investigated. On the basis of the evidence reviewed in this chapter, one is inclined to postulate a model of heredity-predisposition-environmental interaction of some kind, but the links between these agents and the mechanisms of such interaction are, of course, quite unknown. Thus, the genotype may be a predisposition to schizophrenic illness, and the psychosocial environment may set in motion a process that results in the illness. Or the interaction may be more complex. The environment may continuously interact with the genotype to elicit certain kinds of general potentialities and more specific dispositions to react to certain categories of environmental stress that lead to the illness. In brief, genotypic and environmental variables either combine or continually interact and reinforce each other to produce the schizophrenic phenotype.

Suggested Cross References

For further information regarding the various etiological factors that have been proposed for schizophrenia, the reader is referred to Area B, on the basic behavioral sciences, which contains sections on the family and psychiatry, sociology and psychiatry, anthropology and psychiatry, genetics and psychiatry, neurochemistry, and neuropsychology. For further information about the effects of maternal deprivation, see Section 44.1 in Area H, on child psychiatry. Psychoanalytic theory is discussed more fully in Area C, on current theories of personality and psychopathology.

15.4 SCHIZOPHRENIA. IV: CLINICAL FEATURES

HEINZ E. LEHMANN, M.D.

Basic Aspects

There are no objective criteria today for the diagnosis of schizophrenia. But several basic features of this disease have come to be generally accepted since dementia praecox was first described by Kraepelin as a nosological entity at the end of the 19th century. These basic features have served as a foundation for many new psychopathological perspectives developed in recent years and for a deepened understanding of the many and perplexing facets of schizophrenia.

Bleuler described three general primary symptoms of schizophrenia: (1) a disturbance of associations, (2) a disturbance of affect, and (3) a disturbance of activity. Bleuler also has stressed the dereistic attitude of the schizophrenic—that is, his detachment from reality and his consequent autism—and the ambivalence that expresses itself in his affectivity and initiative. Thus, his system of schizophrenia is often referred to as the "four A's": associations, affect, autism, and ambivalence.

Bleuler derived the name of the disease from his concept of splitting. The initiative is split into a variety of equivalent potentialities, and the individual is thus split off from reality; thoughts and associations are fragmented and devoid of meaning; the affect is no longer adequate or appropriate to the situation.

Kurt Schneider, who has probably had the greatest influence on modern German psychiatry, has described a number of first order symptoms of schizophrenia. They are not identical with Bleuler's primary symptoms, nor do they mean the same thing. To Schneider, these first order symptoms of schizophrenia are in no way specific for the disease. However, when a number of these symptoms are present in a patient in whom other pathology—of organic or toxic origin, for instance—can be excluded, then a diagnosis of schizophrenia is indicated. Schneider's first order symptoms include: the hearing of one's thoughts, auditory hallucinations, somatic hallucinations, the experience of having one's thoughts controlled, the spreading of one's

thoughts to others, delusions, and the experience of being controlled or influenced from the outside.

However, schizophrenia could also be diagnosed exclusively on the basis of second order symptoms along with an otherwise typical, clinical appearance. Second order symptoms include: other forms of hallucinations, perplexity, depressive and euphoric disorders of affect, and emotional blunting.

Gruhle proposes still another array of primary symptoms: hallucinations and illusions, a basic disorder of the feeling of identity, strange impulses, delusions, and disturbances of thought and language. Berze defines as primary symptoms all those manifestations that cannot be explained psychologically, but he distinguishes them from the basic schizophrenic disturbance, which he sees as an "asthenia of psychic activity." For Jung, the schizophrenic is characterized by "the assumption of independence by psychic complexes." Janzarik stresses the central significance of paranoid delusions, which he thinks are, for at least some period, an important component of every schizophrenic episode. Wyrsh speaks of schizophrenia as an attack on the center of the personality, and Stransky has coined the descriptive term "intrapsychic ataxia" for the characterization of the schizophrenic individual.

Symbolism. Unquestionably, one of the most characteristic features of schizophrenia is the pronounced symbolism expressed in the patient's behavior, ideation, and speech. This symbolism may be impossible to comprehend for anyone but the patient himself, unless one takes a great deal of time to analyze it. A highly symbolic nature gives the schizophrenic's behavior its often bizarre character.

Schizophrenia has been referred to as a kind of "psychoma," since it consists, particularly in the acute and subacute phases, of a proliferation of psychic productions, like the increased productivity of a malignant growth. This is to be distinguished from the reduced productivity that characterizes the ideational deficit of many other psychiatric diseases, particularly those caused by organic disturbances of brain structure.

Social withdrawal. Almost without exception, schizophrenic patients are characterized by social withdrawal, by the emotional distance one experiences in their presence, and by a lack of capacity for establishing rapport with others. Empathy and sympathy pose greater problems, both for therapists and for schizophrenic patients, than for other psychiatric patients.

Sensitivity. All schizophrenics are, at least originally, more sensitive than the average person. It is likely that this increased sensitivity and heightened responsivity to sensory and emotional stimulation is present in schizophrenics from a very early age, possibly from birth. In this writer's opinion, schizophrenia is characterized by a genetic hypersensitivity to stimuli.

It has been shown experimentally that the schizophrenic patient is bombarded by a greater number of stimuli per time unit than the average normal person. For example, the critical flicker-fusion frequency of an early schizophrenic is higher than that of normal individuals. All other psychiatric disorders are characterized by a decrease in critical flicker-fusion frequency. The schizophrenic patient thus perceives more visual stimuli in a given unit of time than other persons do, and one may hypothesize that this is also true in other sensory modalities. If the schizophrenic's receptor apparatus of greater than average sensitivity is not matched by a central nervous system with better than average ability to process the mass of information coming in, then jamming of the central nervous system may occur through an overload of stimulus input. The schizophrenic's withdrawal may be explained as a defensive maneuver designed to reduce excessive stimulus input.

Whether or not such a theory is accepted, it is well known to those who have worked extensively with schizophrenics that they are extremely sensitive. They are very easily hurt by slightly aggressive or rejecting behavior by others—behavior that, in most cases, would probably not be noticed by a person of normal sensitivity or, if noticed, certainly would not lead to traumatic experiences. In a figurative sense, this supersensitivity could be compared to the supersensitivity of a badly sunburned skin that cannot tolerate even the usually imperceptible pressure of ordinary clothes.

Loss of ego boundaries. Another characteristic feature of most schizophrenic conditions is the loss of ego boundaries. This peculiar symptom may give the patient the delusional conviction that he is reading other people's minds or being controlled by other people's thoughts. It also renders him extremely vulnerable to any kind of external stimulation. His own identity may fuse with that of any object in the universe around him, and he may suffer greatly when he becomes aware of some object in his environment being attacked. Somebody banging the table 20 feet away may cause him to feel almost physical pain or to become infuriated as a personal reaction to such aggressive behavior. (Such loss of ego boundaries also occurs frequently to people who have taken psychotomimetic drugs such as lysergic acid diethylamide (LSD), psilocybin, or mescaline.) This loss of ego boundaries, and thus of identity, produces feelings of depersonalization, followed by experiences of derealization. The resulting loss of contact with reality is the core symptom of any psychosis.

One particular symptom related to a loss of identity is the uncertainty of many schizophrenics about their gender; a male schizophrenic is often not sure whether he is a man or a woman. This uncertainty may be thought of as a regression to the infantile state, before such a differentiation had been established.

Variability. Another strange but specific character-

istic of schizophrenia is its unpredictable variability or inconsistency. A schizophrenic patient may be incapable at a certain time of carrying on a rational, simple conversation, and yet half an hour later he may write a sensible and remarkably well composed letter to a relative. He may refuse to change his shirt for weeks and offend those around him by his strange behavior, but he may, on the same day, display perfect manners when attending a birthday party. He may be unable to figure the right change for a dollar purchase, yet he may be able to play a sophisticated game of bridge or chess.

Symptoms

Perceptual disorders. A variety of perceptual disorders are seen in schizophrenia. It may be hypothesized that these are the result of the schizophrenic's constant exposure to an excessive influx of sensory stimuli. Although the normal individual has a basic, pervasive feeling of familiarity with the environment to which he has become accustomed and adapted—a necessary aspect of all normal perception—the schizophrenic may experience a basic unfamiliarity with his environment. He experiences this unfamiliarity sometimes as a sudden jolt, at other times as a continuous feeling of strange remoteness, as alienation and a lack of closeness.

Because of the unpredictable variability of the schizophrenic's experiences, the Gestalt qualities of the visual world are broken. He frequently sees objects and people change their dimensions, their outline, their brightness from minute to minute or even from second to second in front of his eyes. *Déjà vu* experiences may intrude and produce an uneasy feeling of spurious familiarity. This instability can be shown in experimental investigations on size and brightness constancy, on critical flicker-fusion frequency, on the figure-ground relationship, and on many other perceptual functions.

Hallucinations. Sensory experiences or perceptions without corresponding external stimuli are common symptoms of schizophrenia. Most common are auditory hallucinations, the hearing of voices. Sometimes the voices are those of God or the devil; sometimes they are the voices of relatives or neighbors; and frequently the patient can neither recognize nor understand them. Sometimes there are two or more voices talking about the patient, discussing him in the third person. This particular form of auditory hallucination often appears in schizophrenics who are also alcoholics. Frequently the voices are threatening or obscene and very disturbing to the patient. They may represent some evil outside power over which the patient has no control. Many schizophrenic patients experience the hearing of their own thoughts. When they are reading silently, for example, they may be quite disturbed by hearing every word they are reading clearly spoken to them.

Visual hallucinations occur less frequently in schizo-

phrenic patients, but they are not rare. Patients suffering from organic or affective psychoses experience visual hallucinations primarily at night or during limited periods of the day, but schizophrenic patients hallucinate as much during the day as they do during the night, sometimes almost continuously. They obtain relief only in sleep. When visual hallucinations occur in schizophrenia, they are usually seen nearby, clearly defined, in color, life-size, in three dimensions, and moving.

Tactile, olfactory, and gustatory hallucinations are less common, but it is interesting that visual hallucinations almost never occur by themselves, but always in combination with hallucinations in one of the other sensory modalities. Many clinicians believe that the presence of olfactory hallucinations is indicative of a particularly malignant nature of the schizophrenic process, although there is no decisive statistical evidence for this.

Schizophrenics often experience cenesthetic hallucinations: sensations of altered states in body organs without any special receptor apparatus to explain the sensations—for example, a burning sensation in the brain, a pushing sensation in the abdominal blood vessels, or a cutting sensation in the heart.

The hallucinations may absorb much or all of the patient's attention and may motivate his behavior to a considerable extent. While listening to voices, he may be preoccupied and oblivious to his environment. He may react with laughter or anger or terror, and he may carry on lengthy conversations with the voices.

However, modern treatment methods, particularly pharmacotherapy and social therapies that engage the patient in various activities and no longer leave him all day to his own preoccupations, have robbed hallucinations of much of their vividness and persistence. Also, many patients today know what hallucinations are and know that their hearing of voices may be considered pathological or foolish. Thus, the present day schizophrenic is much less likely to discuss his hallucinations openly than he was only 20 years ago.

Cognitive disorders

Delusions. By definition, delusions are false ideas that cannot be corrected by reasoning and that are idiosyncratic for the patient, that is, not part of his cultural environment. They are among the common symptoms of schizophrenia.

Most frequent are delusions of persecution, which are the key symptom in the paranoid type of schizophrenia. The feeling of being controlled by some unseen mysterious power that exercises its influence from a distance is almost pathognomonic for schizophrenia. It occurs in most, if not all, schizophrenics at one time or another, and for many of them it is a daily experience. The patient who is convinced that he is being persecuted by powerful agencies also often harbors delusions of grandeur; he must be a very impor-

tant person if so much effort is spent on his persecution.

In connection with their experiences of being physically controlled by unseen forces, many schizophrenics have elaborate delusions that telepathy or hypnotism controls their minds as well. The modern schizophrenic often expresses delusions about atomic power, x-rays, or spaceships taking control over his mind and body. Also typical for many schizophrenics are delusional fantasies about the destruction of the world.

Conrad has studied the development of delusions in the schizophrenic patient. In the first phase of the schizophrenic process, which he calls *trema* (German for "stage fright"), the patient becomes aware that something ominous is happening to him. Somehow the world around him is changing, and he himself feels locked in, harassed, and powerless. He may make desperate attempts to regain control through elaborate schemes of body building and character building.

The following is the schedule a young man, aged 19, had set for himself 3 months before he was admitted to a mental hospital in an acute catatonic stupor:

Time	Activity
7:00-8:00	Cold bath, toiletries, bed, dress
8:00-8:15	Encyclopedia (memorize 3 facts)
8:15-8:30	Handwriting
8:30-8:45	Brisk walk
8:45-9:00	Breakfast (1 apple, 1 dish of bran, 2 glasses of milk, 2 glasses of water)
9:00-10:00	Hearing, sight, and scent
10:00-11:00	European, financial, and sport news
11:00-12:00	Wax floors and clean door knobs
12:00-1:00	Cold bath and exercises
1:00-1:30	Geometry
1:30-1:45	Vegetable lunch (very light)
1:45-2:45	Music
2:45-3:45	Walk as far as Atwater and then back to library
3:45-4:45	Study at library
5:00-6:00	Accounting
6:00-6:20	Cold bath
6:20-6:35	Vegetable supper
6:35-8:05	Accounting
8:05-9:00	Hearing, sight, and scent
9:00-9:30	Strength and Health Magazine
9:30-10:00	Wardrobe
10:00-10:20	Cold bath
10:20-10:40	Study vocabulary (12 words)
10:40-11:00	Undress and toiletries
11:00-11:15	Breathing exercise
11:15-11:30	Note improvement in mental fortitude in diary

During the *trema* phase the patient is anxious, irritable, and often depressed. This phase may last for only a few days, but it sometimes lasts for weeks or months. In the latter stages of the *trema* phase, the patient may be in a delusional mood that makes him see his environment in a new and strange light, under which appearances are changed and familiarity is lost.

The *trema* phase is followed by the *apophany* phase, a Greek expression suggesting sudden revelation. (Conrad postulates two phases following the apophanous: the apocalyptic, during which the patient's world becomes more and more fragmented, and the terminal phase.) In the apophanous phase the patient suddenly becomes sure of certain new "facts." A taxi driver this morning touched his cap with his right hand; this meant that he knew where the patient had been last night. A newspaper was lying on the stairs; this meant that his reputation would be ruined before nightfall. A man was feeding two squirrels in the park, indicating that the patient's future would be decided in 2 weeks. Conrad calls such delusions autochthonous, meaning that they are of a primary and irreducible nature. They appear *de novo* and seem to have little or no apparent connection with the patient's life history or with his specific stresses and conflicts.

Why does the patient believe in the reality of these delusions? What is the evidence for the far-fetched connections he mentions? The answer is always the same: "I know it." This direct, immediate, irreducible certainty responsible for the patient's conviction is the irrational, pathological aspect of the primary delusional experience, which, in this author's opinion, cannot be explained by analyzing the patient's conscious or unconscious psychic contents.

Many leading German psychiatrists (Jaspers, Berze, and Gruhle, for example) have emphasized the difference between the formal aspects of a delusion—the primary pathology that is entirely ego-alien—and the contents of the delusion, which have a distinct psychological meaning based on conflicts, drives, and needs in the patient's personality and life history.

Disturbances of thinking. The schizophrenic disturbance of thinking or conceptualization is one of the most characteristic features of this disease.

Von Domarus emphasizes the fact that the schizophrenic may consider two things identical merely because they have identical predicates, that is, certain identical properties. By contrast, in normal logical thought, identity is based on identical subjects and not on identical predicates. The schizophrenic patient may reason, to quote Arieti: "The Virgin Mary was a virgin: I'm a virgin; therefore, I'm the Virgin Mary." It has been shown, however, that this particular logical error is not specific for schizophrenia and is commonly committed by college students when they are distracted or fatigued. Arieti feels that schizophrenic cognition uses isolated segments and parts rather than the whole of the concept.

Matte-Blanco has drawn attention to the pathological symmetry of schizophrenic logic. A schizophrenic patient might reason: "John is Peter's father; therefore, Peter is John's father." Such symmetrical reasoning is sometimes justified; for instance, John is Peter's brother; therefore, Peter is John's brother. But at other times such symmetrical conclusions are not justifi-

fied, and the schizophrenic does not seem to know when he may apply them and when he may not.

The one feature common to all manifestations of schizophrenic thought disorder is that the schizophrenic patient thinks and reasons on his own autistic terms, according to his own intricate private rules of logic. The schizophrenic may be highly intelligent, certainly not confused, and very considerate in his deductions. But his thought processes are strange and do not lead to conclusions based on reality or universal logic.

Storch feels that the schizophrenic uses archaic modes of mystical-magic thinking. Such primitive modes of thinking are closely related to the psychoanalytic concept of primary thought processes that are at work in normal dreaming and allow for condensation, reversal, substitution, displacement, and other distortions of conceptual relationships impossible in rationally controlled thought. Moreau de Tours, in fact, in 1855, compared the psychic processes of a psychotic who is awake to those of a normal person who is dreaming with his eyes open.

Goldstein has described a concretization of thought and a loss of the abstract attitude as typical for schizophrenic thinking. The patient is no longer capable of distinguishing the really important from the irrelevant. He loses his ability to generalize correctly, and he exhibits in the ordering of his concepts a defect

similar to a loss of the figure-ground relationship in perceptual performance. This defect is often brought out by the simple clinical test device of asking the patient to interpret a well known proverb. One schizophrenic interpreted the saying "A stitch in time saves nine" as "I should sew nine buttons on my coat"—an overly personalized and an overly concrete translation.

Cameron has identified overinclusion as a typical feature of the schizophrenic thought disorder. In contrast to the patient whose mental functions are impaired by an organic brain lesion and who tends to omit important items in thought and speech, the schizophrenic tends to include many irrelevant items in his ideational and verbal behavior. This tendency appears to result from a loosening of associations in the schizophrenic patient.

Shakow has demonstrated in a series of experiments that schizophrenics are not capable of holding a set as well as a normal person. This inability becomes evident when schizophrenics are tested for their reaction time in responding to a stimulus that is preceded by a ready signal. In the normal individual the introduction of this ready signal shortens the reaction time to the stimulus that may follow the signal within the next 10 to 15 seconds. But the schizophrenic's reaction time remains the same, whether or not he is warned of

determined by the close procedure, which consists in having other subjects guess words that have been systematically deleted from a continuous speech passage. It is possible to determine the words deleted.

The patient's autistic language

Neologisms. Occasionally, the schizophrenic creates a completely new expression, a neologism, when he needs to express a concept for which no ordinary word exists.

A schizophrenic woman who had been hospitalized for several years kept repeating, in an otherwise quite

one of the

one of the

one of the

ing from a serious disease affecting her nervous system; the component "litters" stood for untidiness or messiness, the way she felt inside; "jitterstitters" reflected her inner nervousness and lack of ease; "leelitla" was a reference to the French *le lit là* (that bed there), meaning that she was both dependent on and feeling handicapped by her illness. This single neologistic production thus enabled the patient to express, in a condensed, autistic manner, information about her preoccupations and apprehensions that otherwise would have taken a whole paragraph to explain in common language.

Mutism. This functional inhibition of speech and vocalization sometimes lasts only for hours or days, but not infrequently it lasts for years or decades in chronic schizophrenics of the catatonic type. Many schizophrenics tend to be monosyllabic and answer questions as briefly as possible. They attempt to restrict contact with the interviewer as much as possible without being altogether uncooperative.

Echolalia. Occasionally, schizophrenic patients exhibit echolalia, repeating in their answers to the interviewer's questions many of the same words the questioner has used. For instance: Examiner: "How did you sleep last night?" Patient: "I slept well last night." Examiner: "Can you tell me the name of your head nurse?" Patient: "The name of my head nurse? The name of my head nurse is Miss Brown."

Echolalia seems to signal two facts: (1) that the patient is aware of some shortcomings in his ideation and (2) that he wishes to maintain an active rapport with the interviewer. He acts much like somebody who is learning a new language and who, in answering his teacher's questions, uses as many of the teacher's words in the strange language as he can possibly manage.

Verbigeration. This is a rare symptom that is found almost exclusively in chronic schizophrenic patients. It consists in the senseless repetition of the same words or phrases, and it may, at times, go on for days.

Stilted language. Some schizophrenics make extraordinary efforts to maintain their social relationships in order to maintain their relatively stable adjustment. But they may betray their rigidity and artificiality in all matters of interpersonal relationships by a peculiarly stilted and grotesquely quaint language. The following excerpt from a letter written by a schizophrenic physician who was hospitalized for more than 15 years is an example of such stilted language:

My dear friend and Professor:

A hearty and cheerful, (Please turn the page over) and a real magnanimous good—morning to you on this first Wednesday of our glorious New Year: And I do hope that our great and our good Lord, and our dearly beloved and kind Shepherd, (Kindly read page three, now). Will be gracious unto both me and thee. I am sure that He will be gracious unto both of us; if He has some sound common sense in His being, this morning. . . . I have not yet heard (Kindly turn over to p. 4, now) from any one of my own colleagues when, I am leaving this noble institution of the healing arts; Nor with whom; Nor through which one

of the portals. Though I am sure that you—as much as any (Kindly turn to page five, now) one else—must be able to enlighten me; very soon, my good old friend. . . .

Behavioral disorders. Changes in a schizophrenic's behavior may be quantitative or qualitative in nature. As an example of quantitative change, the patient usually exhibits a general reduction of energy, spontaneity, and initiative, although in the acute stages he may become excited to the point of threatening his own safety and that of the people around him.

Qualitatively, schizophrenic behavior is usually changed in the direction of poorly coordinated, unpredictable, eccentric, or inappropriate behavior. Most schizophrenics convey the impression of awkwardness and stiffness. One of the earliest signs of incipient schizophrenia in adolescents is sometimes a loss of the natural gracefulness of body movements in walk and gestures.

Mannerisms. Mannerisms of speech and movements are typical for many schizophrenics. So is grimacing, which sometimes is barely noticeable and sometimes is carried to a grotesque degree. In its more subdued form, grimacing may appear as ticlike movements, particularly in the perioral area. In its extreme forms, it can be an elaborate and strenuous regular exercise.

Stuporous states. These occur in the catatonic subtypes of schizophrenia. Until the middle 1930's mental hospitals were filled with stuporous catatonics, many of whom would lie motionless for weeks or months, their eyelids flickering, saliva drooling from their mouths, unresponsive to almost every stimulus. Since they would not take any nourishment, they had to be fed by stomach tube twice a day as long as they remained stuporous. Usually they were incontinent of bladder and bowels. But in some cases there was a persistent retention of urine and impaction of the lower bowel, which made it necessary to catheterize the patients and empty their bowels regularly with enemas.

Today modern physical treatment methods permit psychiatrists to interrupt stupors, usually within a few days, either by electroconvulsive treatment or by pharmacotherapy, and the stuporous patient has become a rare phenomenon.

Also rare today is catalepsy, waxy flexibility, or *flexibilitas cerea*, which was present in many patients 30 years ago. It consists of a waxlike yielding of all the movable parts of the body to any efforts made to place them in certain positions. Once placed in position, the arm, leg, or head remains in that position for a long time, sometimes for hours, even if the position is uncomfortable for the patient.

Catatonic patients also used to exhibit the phenomenon of the "psychic pillow": when lying in bed, their head would remain elevated several inches above the pillow as long as they were awake.

Many chronic schizophrenics still show a very pronounced lack of spontaneity and move only rarely or

only when specifically asked to do certain things. However, a patient who shows almost no response to his environment is definitely capable of acutely perceiving what is going on around him. Even a patient in a complete stupor may, several months later, recall every word of a conversation carried on in front of him while he appeared to be in a state of unconsciousness.

Patients who have recovered from such a stupor report afterwards that, although they were keenly aware of everything going on around them, they were unable to make the expected responses they very much wanted to make. It had been as though a strange power was holding them back. If one asks a stuporous patient to perform a certain movement, for instance, to extend his hand, slight oscillating movements of his arm can often be detected. It is as though the patient is caught in a tug of war between the muscles responsible for the extension of his arm and the antagonist muscles, which seem to be innervated at the same time. One might think of this phenomenon as schizophrenic ambivalence expressed in the motor sphere.

Echopraxia. This motor symptom is analogous to echolalia in the verbal sphere: imitation of movements and gestures of a person the schizophrenic is observing.

Automatic obedience. Another symptom sometimes observed in catatonic patients is automatic obedience. A patient may, without hesitation and in a robot-like fashion, carry out most simple commands given to him.

Negativism. The term negativism refers to patient's failure to cooperate, without any apparent reason for this failure. The patient does not appear to be fatigued, depressed, suspicious, or angry. He is obviously capable of physical movement. But he fails to carry out even the simplest request. Sometimes he may even do the opposite of what he is asked; for instance, he will lower his hand when one requests him to raise it, push the spoon away instead of putting it into his mouth.

Most patients presenting these motor phenomena characteristic of the stuporous catatonic are also almost completely mute or very restricted in their verbal productions.

Stereotyped behavior. This is occasionally seen in chronic schizophrenics in the terminal stages of their disease. It may present itself as repetitive patterns of moving or walking, perhaps pacing in the same circle day in and day out. Or it may be the repetitive performance of strange gestures. Or the patient may again and again, sometimes over a period of years, use the same phrases, ask the same questions, make the same comments. Such stereotyped speech should be distinguished from the symptoms termed perseveration of ideas or verbigeration.

Before the advent of effective physical therapies for schizophrenia, Klaesi, in a classical monograph on stereotypies in schizophrenia, concluded that the number of stereotypies observed on a given ward is in-

versely related to the therapeutic care prevailing on the ward. Even without physical treatment methods, stereotyped behavior of schizophrenic patients can be prevented and counteracted effectively by personal attention and social therapies—occupational therapy, recreational therapy, and industrial therapy.

Deteriorated appearance and manners. Schizophrenic patients tend to deteriorate in their appearance. Their efforts at grooming and self-care may become minimal, and they may have to be reminded to wash, bathe, shave, change their underwear, etc. Some schizophrenic men have a particular aversion to having their hair cut or changing their shirt or suit. One schizophrenic adolescent wounded his mother severely with a knife because she kept on nagging him about changing his shirt.

In general, schizophrenics do not have much respect for the social amenities. They may not return a greeting or a smile, they may not carry their part in a conversation, they may exhibit crude table manners and show, in many other ways, their lack of consideration for the presence and feelings of others. Chronic and regressed schizophrenics often masturbate openly in public, which was formerly considered by psychiatrists to be more of a moral and a medical than a social problem.

Affective disorders. As in the sphere of behavioral disorders, affective disorders in the schizophrenic are characterized by quantitative and qualitative changes.

Reduced emotional responses. The quantitative change invariably consists in a reduction of the intensity of emotional responses. Many schizophrenics appear to be indifferent or, at times, totally apathetic. Others with less marked emotional blunting show at least some emotional shallowness or a certain lack of depth of feeling.

Inexperienced observers should, however, be extremely hesitant to make judgments in the highly subjective area of normal emotional depth. What is normal emotional expression in an Anglo-Saxon culture, for example, may suggest a schizoid reduction of emotional response in a Mediterranean culture, and a normal range of emotional expression in a Latin culture may appear to the Anglo-Saxon observer as hysterically exalted.

Although the evaluation of a schizophrenic patient's emotional reaction may serve as one of the most valuable diagnostic criteria, it is also frequently the least reliable of all observed data and should, therefore, be treated with considerable caution by any but the most experienced diagnosticians. On the other hand, the patient himself often offers valuable and valid information about his own gradual decrease in the ability to experience empathy, which he may have observed introspectively long before it became clinically evident.

Inappropriate responses. A typical emotional reaction of the schizophrenic is an incongruous or inappropriate response to life situations. A schizophrenic

patient may talk about his child's death with a broad smile, or he may react with rage to a simple question about how he slept last night. This splitting or dissociation of the affective response from the cognitive content is almost pathognomonic for schizophrenia. It is a dramatic and always disconcerting experience for the observer who regards the appropriate emotional response to a given mental content as one of the most solidly founded aspects of the sane mind.

However, the schizophrenic who expresses an inappropriate emotional reaction does not necessarily experience the particular emotion his behavior conveys. Normal individuals under the influence of LSD frequently report that they find themselves in the frightening situation of being anxious, but not able to express this anxiety properly. Each time they start to describe it, they begin smiling or laughing. This response is similar to the neurological phenomenon of paraphasia, the organic brain symptom that prevents the stricken individual from using the correct words for the concepts he wants to express.

One might consider the inappropriate emotional reaction as simply a breakdown in the translation of the person's private experience into its normal public performance—a parathymia. The possibility must certainly be considered that many schizophrenics who smilingly talk about serious or anxiety-producing subjects experience subjectively a vivid and appropriate emotion but fail utterly in expressing it normally.

The degree of emotional blunting and inappropriateness of a schizophrenic's emotional reaction are among the most telling measures of the extent to which the schizophrenic process has invaded a person's personality. With the exception of a very acute schizophrenic breakdown, an inappropriate emotional reaction indicates that the schizophrenic process has made considerable inroads into an individual's personality structure. Emotional blunting reflects closely the degree of personality deterioration in a chronic schizophrenic. Conversely, appropriate emotional reactions and a well preserved emotional response are always a favorable prognostic sign in schizophrenia.

Abnormal emotions. Schizophrenia not only alters emotional reactions to external stimuli, but it may also induce strange emotions and moods that are seldom, if ever, experienced under normal conditions. For instance, states of exaltation with feelings of omnipotence, "oceanic" feelings of oneness with the universe, religious ecstasies, terrifying apprehensions about the disintegration of one's own personality, anxious moods when the catastrophic destruction of the universe seems to be impending—all of these are emotional experiences occurring in different stages of schizophrenia, but they are most frequently encountered in the acute phases of the breakdown. LSD and other psychotomimetic drugs may temporarily generate similar experiences in normal subjects.

Somatic symptoms. There are no specific somatic manifestations in schizophrenia. However, in the early

stages of the disease, patients often complain of a multitude of symptoms—headache, rheumatic pains in the shoulders, back strain, weakness, and indigestion. They are sometimes treated for months for neurasthenia or are considered to be hypochondriacs or malingerers.

Once the disease is fully developed, a schizophrenic patient is, according to some authors, less likely to develop a psychosomatic disease than the average individual. Schizophrenic patients also seem to suffer less frequently than others from various allergies. On the other hand, they are more likely to develop tuberculosis. Before the days of antibiotic treatment, a high proportion of schizophrenic patients succumbed to tuberculosis. The increased susceptibility of the schizophrenic to tuberculosis may have been due to both constitutional and environmental factors. Many schizophrenics are of the asthenic body build, a type constitutionally more susceptible to tuberculosis than other body types. In addition, the schizophrenic patients' confined and inactive existence in often overcrowded mental hospitals provided an environmental factor that favored the development of tuberculosis.

Many chronic schizophrenic patients, particularly the severely regressed ones, suffer from chronic constipation to the point of developing impaction of the lower bowel, eventually resulting in a megacolon. X-ray pictures of the bowels of these patients closely resemble those of patients with Hirschsprung's disease. With inadequate nursing supervision, such patients may develop acute abdominal complications, for example, a volvulus or paralytic ileus that may not be diagnosed for some time because the patient himself may be so uncommunicative that he fails to express any complaints.

Similarly, uncommunicative chronic schizophrenics may remain ambulatory for days with an acutely inflamed appendix, which may be diagnosed only after the uncomplaining patient has collapsed in the dining room following a rupture of the appendix into the peritoneum. For the same reason, inadequate self-reporting, schizophrenic patients are more likely than others to have silent coronary attacks and myocardial infarction.

A patient suffering an acute schizophrenic breakdown will almost certainly present the autonomic triad of dilated pupils, moist palms, and moderate tachycardia. He also often has a systolic blood pressure 10 to 20 mm. above the norm. These signs of sympathetic excitation may be present even if the patient shows no outward signs of increased emotional tension—another manifestation of prevailing functional dissociation.

It is strange that many acute schizophrenic patients, unless they are extremely excited, sleep well the night following their admission to the hospital. By contrast, few persons suffering from any other physical or mental disease can manage to sleep well during the first night after admission to a hospital.

Acrocyanosis. This condition plagued mental hospi-

tal patients and perplexed their psychiatrists 25 and more years ago. The symptom occurred in many chronic schizophrenic patients, particularly in chronic catatonics, who would sit, stand, or hunch motionlessly all day long. The lower portion of their legs was edematous, cold, and cyanotic; and the same condition often affected their hands.

For a long time, it was thought that acrocyanosis reflected an autonomic disturbance specifically related to the pathological substrate of the schizophrenic process. Later, it was discovered that this condition was simply the result of circulatory stasis, which was, in turn, the result of the patient's almost complete immobility. A similar condition could be produced experimentally in normal volunteers maintaining their extremities motionless for long periods of time.

In modern mental hospitals where most patients are kept active during the day, acrocyanosis has become a very rare phenomenon. Nor does the modern hospital psychiatrist see any more of the ankyloses and kyphoses due to chronically maintained pathological postures in catatonic patients.

Constitutional characteristics. The relationship between body build and personality structure or certain types of mental illness has been intensively studied for many years. Kretschmer was the first to bring convincing evidence of such relationships. He showed that schizophrenia occurred more frequently in persons of asthenic (leptosomic), athletic, and dysplastic body types than in the pyknic type. The pyknic type was more likely to develop manic-depressive psychosis than schizophrenia.

The leptosomic person is characteristically thin, with a long, pointed face, long extremities, a flat chest, and poor muscular development. The athletic person has a broad, bony face, strong jaw, a wide thorax, and well developed musculature. The pyknic person tends to be shorter, round, perhaps even stout, with comparatively small hands and feet but a wide chest and a well developed abdomen. The dysplastics do not fit readily into any of these categories.

Sheldon established more precise methods for measuring the various body types and reclassified the leptosomics, athletics, and pyknics into ectomorphics, mesomorphics, and endomorphics, respectively. In Sheldon's classification, schizophrenics would tend to be ectomorphics, mesomorphics, and dysplastics.

Syndromes

Kraepelin, in carving out the two major diagnostic concepts of dementia praecox and manic-depressive psychosis, distinguished and described three basic subtypes of dementia praecox: the catatonic, the hebephrenic, and the paranoid. Each of these types had previously been described by French or German clinicians as a separate mental disease. Bleuler later added schizophrenia simplex as a fourth basic type of schizophrenia.

These four major subtypes of schizophrenia are no more than a convenient shorthand of behavioral description based on syndromes or symptom patterns. No physical substrates for these reactions are known. In every subtype there may—and usually do—occur a variety of schizophrenic symptoms in addition to those especially characteristic of the given subtype. Many patients change from one subtype to another, from, say, paranoid to hebephrenic, or from catatonic to paranoid. Clear cut examples of the various schizophrenic reaction types are best found among chronic patients who, over many years, have crystallized a distinct form of behavior.

Since Bleuler, many other types of schizophrenia have been named and described. Some of them are officially accepted in the *Diagnostic and Statistical Manual* of the American Psychiatric Association. Others are recognized in the International Statistical Classification. And still others can be found in the psychiatric literature. This section briefly outlines the four basic subtypes and some of the other better known types of schizophrenia and gives case histories to illustrate them.

Many acute schizophrenic breakdowns cannot be properly classified because they show such a wide variety of schizophrenic symptoms. For statistical purposes such patients are classified as undifferentiated schizophrenics. Even among chronic schizophrenics, not every patient can be readily pigeonholed. He may show the silly behavior of a hebephrenic, assume at times catatonic postures, and also harbor a system of paranoid delusions. He would then be diagnosed as undifferentiated, chronic.

The catatonic and hebephrenic subgroups are often referred to as nuclear schizophrenia because their manifestations are most specific for the essentially schizophrenic deviations in affect, association processes and behavior, and because these groups are most regularly associated with the typical preschizophrenic personality. Furthermore, they most frequently end in personality deterioration, which for Kraepelin was the principal criterion of his dementia praecox concept.

Catatonia. Catatonic schizophrenia occurs in two forms: (1) stuporous catatonia and (2) excited catatonia. The essential feature of both forms is the marked abnormality of motor behavior.

Stuporous catatonia. The stuporous catatonic may be in a state of complete stupor, or he may show a pronounced decrease of spontaneous movements and activity. He may be mute or nearly so, and he may show distinct negativism, stereotypies, echopraxia, and automatic obedience. However, even after standing or sitting motionless for long periods of time, perhaps for weeks, he may suddenly and without provocation have a brief outburst of destructive violence. Some catatonic schizophrenics exhibit the phenomenon of catalepsy (waxy flexibility). (See Figure 4.)

A patient in a state of complete catatonic stupor can usually be roused from it in a dramatic manner

by intravenous injection of sodium Amytal or another short-acting barbiturate. Within minutes, the patient's frozen facial expression changes to one of normal animation. He begins to talk and move about normally and in many instances becomes, for an hour or two, relatively lucid. The total inhibition of the patient in catatonic stupor may be the result of excessive cerebral excitatory processes. Like an engine racing so wildly that one cannot put in the clutch, this excess prevents the person from performing and behaving in a normal manner until his excessive cerebral functions have been reduced by a chemical agent that has a depressing effect on brain metabolism. But, spectacular as the immediate results appear to be, the technique has no significant therapeutic value.

A young, unmarried woman, aged 20, was admitted to a psychiatric hospital because she had become violent to her parents, had been observed gazing into space with a rapt expression, and had been talking to invisible persons. She had been seen to strike odd postures. Her speech had become incoherent.

She had been a good student at high school, then went to business school, and a year before admission started to work in an office as a stenographer. She had always been shy, and, although she was quite attractive, she had not been dating much. Another girl, who worked in the same office, told her about boys and petting and began to exert a great deal of influence over the patient. The second girl could communicate with her from across the room. Even when they went home at night, the patient would get voice messages telling her to do certain things.

FIGURE 4. Chronic catatonic patient. This patient is immobile, demonstrating waxy flexibility. Note the uncomfortable position of her arm, which is elevated without support, and her stony facial expression with *Schnauzkrampf* or frozen pout.

Finally, pictures began to appear on the wall, most of them ugly and sneering. These pictures had names. One was named shyness, another distress, another envy. Her office friend sent her messages to knock at the wall so as to hit these pictures.

The patient was agitated, noisy, and uncooperative in the hospital for several weeks after she arrived and required sedation. She was given a course of insulin coma therapy, with no significant or sustained improvement. Later she received several courses of electroconvulsive treatment, which also failed to influence the schizophrenic process to any significant degree. Ten years later, when neuroleptic drugs became available, she received pharmacotherapy.

Despite all these therapeutic efforts, her condition throughout her 20 years of stay in a mental hospital has remained one of chronic catatonic stupor. She is mute and practically devoid of any spontaneity, but she cooperates with simple requests. She will stay in the same position for hours or sit in a chair in a curled-up position. Her facial expression is fixed and stony.

Excited catatonia. The excited catatonic is in a state of extreme psychomotor agitation. He talks and shouts almost continuously. His verbal productions are often incoherent, and his behavior seems to be influenced more by inner stimuli than by responses to his environment. Patients in catatonic excitement urgently require physical and medical control, since they are often destructive and violent to others, and their dangerous excitement can cause them to injure themselves or to collapse from complete exhaustion.

An unmarried man, aged 27, had been working as a teacher and was admitted to a psychiatric hospital because he had become increasingly agitated and irrational following several nights of wakefulness. He was extremely talkative and ran about aimlessly. His behavior became very strange; for instance, he tried to clean everything in the house, moved his wristwatch up to his shoulder, stripped his clothes off, chewed large wads of paper on the grounds that this was good for him, talked about killing himself, then said that he might already be dead.

He heard voices ordering him about incessantly and frequently laughed without any apparent cause. After chewing the paper he would spit in it and then drink his saliva. He rolled into odd postures on the bed with his tongue sticking out. He started to jump and dance when taken to the bathroom by a nursing assistant for a shower and became destructive to the bathroom furnishings. His gait was manneristic. His speech was utterly incomprehensible. He refused to take any medication and had to be sedated by parenteral medication.

He remained noisy, excited, destructive, and irrational in his behavior for a month, then improved in response to high doses of neuroleptic medication and a few electroconvulsive treatments. Three months after admission, he was discharged from the hospital, symptom-free and with good insight into the nature of his illness. For the last 2 years he has been employed as a teacher. He attends a psychiatric after-care clinic every six weeks and is on maintenance pharmacotherapy.

Stauder gave the name pernicious or fatal catatonia to those excited catatonic states that could not be controlled by classical sedation. Patients suffering from this condition would often succumb to it within a week or two. The danger was particularly great in the summer during a heat wave because, prior to the advent of neuroleptics, sedatives in high doses would often interfere with thermoregulatory centers in the hypothalamus, and the patient would die in a state of acute hyperthermia. Losing such a patient in the past was es-

pecially tragic because the psychiatrist knew that his patient had a good chance to recover from his schizophrenia if he could keep him alive for a few months during the critical stage. Today such patients can be carried safely through the critical period of acute excitement with electroconvulsive treatment and modern pharmacotherapy.

Periodic catatonia. A rare but intriguing form of catatonia is the periodic catatonia. Gjessing studied this disease over many years and in a beautifully conceived and systematically controlled investigation proved that motor functions, ideation, and perception in periodic catatonia were closely linked to the patients' changing levels of positive or negative nitrogen balance. Patients affected with this disease have periodic recurrences of stuporous or excited catatonic states. Each recurrence of catatonic behavior is associated with extreme shifts in the patient's metabolic nitrogen balance.

Gjessing also found that relapses in such patients could be prevented by regulating their nitrogen balance through continuous administration of thyroxine. However, these metabolic and therapeutic observations apply only to patients suffering from periodic catatonia, and most schizophrenic patients who present catatonic symptoms do not fall into this category. Most of the cases of periodic catatonia seen in recent years have also responded well to neuroleptic medication, and relapses were usually prevented by neuroleptic maintenance medication.

Hebephrenia. The hebephrenic subtype is characterized by a marked regression to primitive, uninhibited, and unorganized behavior. The hebephrenic patient is usually active but in an aimless, nonconstructive manner. His thought disorder is very pronounced, and his contact with reality is extremely poor. His personal appearance and his social behavior are dilapidated. His emotional responses are inappropriate, and he often bursts out laughing without any apparent reason. Grinning and grimacing are commonly seen in this type of patient, whose behavior is best described as silly or fatuous. (See Figure 5.)

A 15-year-old girl attended a summer camp, where she had difficulties getting along with the other children and developed animosity toward one of the counselors. On her return home she refused to listen to her parents and she heard the voice of a man talking to her, although she could not see him. She rapidly began to show bizarre behavior, characterized by grimacing, violent outbursts, and inability to take care of herself.

Her school record had always been good, and she was fluent in three languages. Her parents described her as having been a quiet, rather shut-in child with no abnormal traits in childhood. Family relations were reported as having been satisfactory.

On admission to a psychiatric hospital, the patient's speech was incoherent. She showed marked disturbances of formal thinking and blocking of thoughts. She was impulsive and appeared to be hallucinating. She stated that she heard voices in her right ear and that a popular singer was running after her with a knife. She also thought that her father was intent on killing her. She thought that she was pregnant because she had hugged one of the residents.

Two months of neuroleptic treatment brought no apparent improvement. She was then given a course of very intensive electroconvulsive therapy and continuous sleep treatment. Over a period of a year she received close to 200 electroconvulsive treatments and 50 subcoma insulin treatments—without improvement. She was then transferred to another mental hospital, where her behavior has, for more than a year and a half, continued to be very disturbed.

She is often incontinent and most of the time neglects her physical appearance. But occasionally she will spend hours dressing herself, looking in the mirror, and putting on excessive makeup. At times she has been seen eating her feces. Occasionally she adopts the roles of a singer or dancer. She makes statements like: "Will I live forever? Nurse, I didn't throw my love away. It is in my stomach and it hurts." In the dining room she attempts to grasp the genitals of male patients. High doses of neuroleptics are continuously required to control her behavior. The ultimate prognosis is very poor.

Paranoid type. The paranoid type of schizophrenia is characterized mainly by the presence of delusions of persecution or grandeur. Paranoid schizophrenics are usually older than catatonics or hebephrenics when they break down; that is, they are usually in their late twenties or in their thirties. Patients who have been well up to that age have usually established a place and an identity for themselves in the community. Their ego resources are greater than those of catatonic and hebephrenic patients. Paranoid patients show less regression of mental faculties, emotional response, and behavior than the other three subtypes of schizophrenia.

A typical paranoid patient is suspicious, guarded,

FIGURE 5. Hebephrenic patient. Posturing, grimacing, and mirror-gazing are symptomatic of the disease.

and reserved. Often he is also hostile and aggressive. Socially, the paranoid patient usually conducts himself quite well. His intelligence in areas not invaded by his delusions may remain high. Paul Morphy, an American chess champion in the first half of the last century and one of the greatest chess masters in history, developed paranoid schizophrenia in his middle twenties and was hospitalized for years. But even many years after he had become ill, he still played an original and masterful game of chess if he could be persuaded to accept the challenge.

An unmarried woman, aged 36, who had held a good position as a secretary for several years became convinced that she was engaged to a man working in the same office. This man was married, but she "knew" that his marriage was to be annulled. She then began to feel persecuted by many people in her environment and started to hallucinate. She was admitted to a mental hospital, where she received insulin coma treatment. She improved but never sufficiently to be discharged from the hospital. Three years later she died from carcinoma.

She wrote a detailed account of her experiences in the early stages of her psychotic breakdown. The following excerpt, reported with almost sober detachment yet without any real insight, is a gripping description of the eerie transformation of the paranoid schizophrenic's world of everyday reality into one of menacing and unpredictable catastrophe.

"This was in the morning. My shoes had been taken across the street to the shoemakers and that evening around five o'clock I went for them and as I came out into the Court way, I heard someone say, who was evidently in one of the apartments 'There she is.' I had to wait quite a while in the store and on coming back into the Apartment House, there were about eight or nine people going out, mostly women. It looked to me as if they thought I was getting in touch with someone and thought they had better leave. I heard a woman say 'you will go crazy yet...'

That night I wrote a letter to my Aunt (in the United States) and mailed it in the Post Office at the corner of University and St. Catherine Streets. I came back home and in about twenty minutes I heard the letter read and discussed from some apartment in the Building. I had mentioned my sister's name in the letter and they wanted to know who she was. I asked my Aunt to mail any letters she sent to me to my sister's house as I felt that the Janitor was helping these people. I heard Mr. B. say 'See what she says about me but never mind I can clear myself.' They also discussed whether they would send it on or not. My Aunt has since told me that she received that letter. My people think this was imagination but it certainly was not. ... I stood in the stairway looking out of the window for a while and I saw a flash as if my picture had been taken. I looked up at the roof to see if there was anybody there and I heard a woman say 'Go ahead look right into it.' I went to go up the stairs to phone for the police when I heard a commotion in the hall. It sounded as if someone was leaving one apartment and going into another. I went back and stood for a while outside the door of Apartment 9. I heard someone say that a letter had been written by someone, who had signed my name, to Mr. D., but she did not have the nerve to send it. Then I rapped on the door very hard and told them to open the door. A woman opened it and I saw a man sitting on the chesterfield. There seemed very little in the house. There was a sewing machine. I had often heard the scissors being put down on the machine when I was in my own apartment. Therefore, it must have been the apartment where the voices were coming from all the time. ... The landlord came then and I told him, and my Mother came down the stairs and they took me back to my apartment. My Mother made the remark to the landlord that 'I was a very sick girl.' I suppose Mr. B. had led her to believe I was going out of my mind.

When my sister and her husband came, her husband asked me not to be angry but that he had telephoned for the doctor. The doctor came and I told him part of what happened. He examined me and then spoke privately to my sister and Mother. I do not know what he said. He asked me if I had been sleeping well. I told him I had not. It had been quite impossible to sleep with all that going on. He gave me a prescription, which my brother-in-law took to the druggist and had filled out. My sister asked me to go to her place which I did. ... Upon retiring I took one pill. ... which seemed to have a terrible effect on my mind during the night. I felt quite ill when I got up the next morning, as I was drugged. I had also been followed to her place and it seemed as if Mrs. D. was somewhere in the Apartment Building. It seemed to me that they had some instrument by which they could look into the house. Then I heard them say something about throwing acid in my face. There was a man and a woman coming up the fire-escapes, giving me the impression that they had acid to throw into the room. I had pulled down the shade of the bedroom, having the impression that they could see into the room, and stood waiting. I heard someone say 'Get down out of there.'

Then my sister told me that the doctor wanted to see me again. I told her I did not want to go but she persuaded me to go. When on the street it seemed to me that a lot of people knew about this affair. I got the impression that they had got my picture and that in some way it had been circulated around. While in the doctor's office I heard someone say 'Well, she don't talk very much anyway.' At the time I took for granted it was some of the men talking. The doctor examined my nose and head a bit. He then suggested that I go and get an X-Ray and sent me to Doctor M. Dr. M. lived in an Apartment House, if I am not mistaken, on P. Avenue. On coming through the hallway to the stair-case I heard a man say 'We are doing all we can.' He came running down the stairs and asked us if we were looking for Dr. M. My sister said 'yes' and he told us where to go. I, of course, was quite upset over this and got suspicious of Dr. M. He showed us different X-Ray pictures. I stood looking at them for awhile and then decided I would not have an X-Ray. I told the doctor so and started to walk out of the office. My sister shoved me towards him and he held me by the wrist. I took his hand off and told him that I was paying for this and would say when I would have it done. I then walked out of the office. My sister stayed back and then I got quite upset over her, thinking he might do something to her. I went back and screamed for her to come out. She came out and on my way home she cried and said she did not know what to do with me. I told her not to force me into anything and when I asked her to come out of a place to please come. I also told her that I was fighting for my life.

When I got back to my sister's apartment, I was sitting in the living room, when I heard some people talking, which sounded as if the voices were coming from the Apartment beneath us, pretending they had again waylaid Mr. D. and that they were taking in some flowers which were supposed to be for me and they were talking about some lies he was supposed to have told. I went to my sister and said 'There, they are at it again.' I opened the door and there were two people standing in the hallway and I heard them say 'They are not for here' which I took for granted they were referring to the flowers. ... I went to see Dr. Z in the Medical Arts Bldg. When getting off the car, I heard someone say 'I am glad she is getting off here.' I went into the office and waited for Dr. Z. The longer I waited the more I felt like walking out of the office. Anyway he came in and started asking me quite a few questions and he led the conversation to Mr. D. I told him that his marriage was annulled and I was going to marry him. He said 'What would you do if I told you his marriage was not annulled?' I told him I thought I would die. I told him that all I needed was a tonic for my nerves. He wrote out a prescription. He said to me that that he wanted to speak to my sister alone. She told me afterwards that he said he could send me to the ... Hospital but that he doubted that he could do anything.

On my way home we stopped at the Drug Store.... On hearing a girl who was standing in the store say 'You are lucky' I felt my life was being threatened and I would not get what the doctor prescribed. I felt sure that they were now anxious to do some bodily harm to me.... On the streetcar on my way home from the doctor's I heard a girl say to the man she was with 'Maybe they will make a monk out of him' and saying something about me being strong. They evidently had expected some results from the pills I was taking and most likely knew exactly what they were. Well, I started for my sister's home and on the streetcar again there were two women talking. I did not know them at all. They were looking my direction and one woman said to the other 'She is always looking for a fight.' They changed their seats to the same side as I was on and I heard one of them say 'He will never marry her.' One of the women followed me into the grocery store. The man at the counter said 'Maybe they will put your heart on a platter.' Saying that out loud but to no one in particular... I seemed to be known wherever I went. When I thought of what I had heard on the streetcar about making a monk out of him, of course meaning Mr. D., I started to cry. My sister asked me what was the matter and at last I told them that 'They were going to make a monk out of him.' They tried to console me and my cousin asked if I would care to go to his place. So we went there. I was quietening down but I think my cousin thought I was going out of my mind and took me to his desk, which was the same style as mine and opened and shut a drawer. I then seemed to have gone into a trance because I had no control over what I said or did. Mrs. D. had made the remark 'Put her into a trance and then she will talk.' This was before I had seen any doctor. I pulled the drawer out and pulled out a paper with a lot of figures on it, which I thought was Mr. D.'s. I was staring at it when my cousin told me it was his and I said 'Oh' and put it back. I went into the living room and called for Mr. D. and I started to talk and could not stop. I said that they made a fool of me in the office. I also said I had to go away but would be back again. I talked pretty near all night. I had the queerest sensation as if something had been applied to my feet, also as if some terrible evil was going on. Then I heard people talking and knew that I was still being followed. I was too nervous to go and get my hair dressed in case they would deliberately burn it. I knew that they could hear everything I said and they bothered me quite a bit with their talking. I asked my Mother to come back to our apartment with me. I tried to whisper it so they would not hear me but she could not understand, so I wrote it. I got so I would not speak very much except to ask her to come home with me. I went to lie down and immediately I did so, I felt as if my mind was being read. I moved my head from side to side trying to make myself stop thinking. I finally went to sleep but got up again telling my sister that I felt I had been hypnotized and started to walk up and down. I knew they could tell what I was thinking, so I started to think things to myself which was not very complimentary to a Roman Catholic. They laughed and said they would tell the Pope. I was talking to my sister in between times and then they started to wonder if I was talking to myself or really carrying on a conversation with someone. I heard someone come to the door to listen. I would have opened it but I did not want to disturb my sister any more than what was already done. After a while I went back to bed when I jumped up again I felt as if something was happening to one side of my face. I looked in the mirror but there was nothing the matter. Sunday morning I started to get ready to go when I again went into something like a trance. I then started to see things, such as the Altar of the Anglican Church and other things and again I started to talk. It seemed as if my future life was being revealed...."

Another paranoid woman who had been hospitalized for 3 years wrote the letter that is reproduced in part below. Like many schizophrenics, this patient is tortured by the experience of being influenced in her

bodily functions through fiendish devices employed by her enemies.

Dear Dr.:

It is with the nurse's knowledge that I write this letter to you, regretting at the same time to trouble you about a maladjustment that need not occur. I am at a loss to understand why, those who are responsible are permitted to indulge in this peculiar pastime. Perhaps those with some authority do not desire to check it, but I realize, in any case, that it is rather difficult to do so inasmuch as when one person is checked, she passes the job on to someone else—and so it goes on, practiced first by one and then another. I refer to this instrument they use that completely locks up the intestines and prevents them from eliminating at all even with a laxative, which is useless to take in such circumstances. It also twists me between my legs occasioning much discomfort, preventing proper rest in bed when my body is so tightened up that it is impossible to relax. I spoke to you several days ago about unexplainable solutions being injected into my body and my rest disturbed continually during the night. You agreed that if any treatments were ordered they should not take place at these hours. I think you said you would find out about any such requirement or order. Well, the hour of interference has changed—interference is the right word to use because the one whoever is responsible is doing a great deal of harm. I am awakened every morning to the exact minute about 5.30. About 6 o'clock I drop off again until 7 am (breakfast not until 8 am) During this interval some person interferes with both passages of my body, and I find myself going around the rest of the day like a tank-full of burning Salt Water but quite unable to eliminate at 5.30. I am quite comfortable but if I arose at that time, I suppose something would take place in the washroom—as these things so often do. The bladder is also interfered with as is indeed every organ in my body with which I have never had any previous trouble. This has taken place nearly every day this week. If they do not get a chance just before I retire, some person in my room, by arrangement I suppose, awaits for me to get out of bed and as soon as I turn my back to them quickly uses this instrument, so as to insure this locked-up condition of the abdominal region. Because of so much interference, it is sometimes necessary for me to encourage the bladder to completely empty by means of the application of heat in the form of towels rung out in hot water and this is only effective in a standing up position—There is obviously some solution injected and as soon as I have withdrawn it in this manner I am very comfortable, but am not allowed to remain that way long. Something has also taken place this week which has been done once before on this ward and once in West House where it was frowned upon after discovery. I have been fixed up—temporarily I hope if the above results are going to continue—with two separate outlets for urination, which almost appears to come through two holes in the pelvic bone. All these months, as the previous nurses know, I have had to endure endless damage by interference with the pelvic. Perhaps they have got tired of that at last—and now it has to be something else, and when they get tired of that what next?... There are other means of displacing the intestines, not only by instruments in the hands of other inmates, but by other mechanical tricks probably operated by the same people. Why I should be locked up at all I cannot imagine, since my tendency is to the reverse nor have I yet experienced any weakness of the bladder. Some of the people in my room do not give others much peace, but it is also done by others elsewhere on the ward. When they see me taking a laxative at the first opportunity they lock me up so as to prevent any results which there would be and....

In both of these reports, sexual conflicts have clearly influenced many of the patients' delusional and hallucinatory experiences. In the second report it is not difficult to detect repressed homosexual conflicts.

Repressed homosexuality is, according to psychoanalytic theory, primarily responsible for the need to employ the defense of projection, through which the paranoid psychotic elaborates his delusions of persecution.

The term paraphrenia is often used to describe chronic schizophrenic conditions characterized almost entirely by the presence of well systematized delusions that often remain unchanged in content for years. Paraphrenic patients are distinguished from nonschizophrenic chronic paranoids by the unrealistic, fantastic, sometimes bizarre, and never plausible nature of their delusions. The personalities of paraphrenic patients, on the other hand, are usually well preserved, and the patients are often quite happily adjusted to their life situations. In fact, many paraphrenics seem to derive considerable satisfaction from their delusions, which are more often of a grandiose than of a persecutory nature.

A 33-year-old unmarried woman had an acute psychotic breakdown characterized by many rapidly changing delusions of persecution. She showed a moderate response to insulin coma therapy, but she has remained hospitalized for more than 15 years.

Visitors to the hospital regularly consider her to be one of the hospital staff members. She holds an important and responsible position in the dietician's department, where she is one of the most competent and reliable workers. She is very helpful to the nurses on the ward. She is an excellent organizer of major social functions for the patients. She writes clever poems to be read at good-bye parties for staff members who leave the hospital employ after long service.

In short, she is a happy, constructive, and productive person with a good deal of charm, but she has been convinced for more than 10 years that she is married to a French count, that she owns property worth many millions of dollars, and that she came to the hospital in order to teach the patients ballet.

Simple type. The simple schizophrenic's principal disorder is a gradual, insidious loss of drive, interest, ambition, and initiative. He is usually not hallucinated or delusional, and, if these symptoms do occur, they do not persist. He withdraws from contact with other people, tends to stay in his room, avoids eating or meeting with other members of the family, and stops seeing his friends. He stops working. If he is still in school, his marks drop to a very low level, even if they were consistently high in the past.

The patient avoids going out into the street during the day but may go for long walks by himself at 2:00 and 3:00 in the morning. He tends to sleep until noon or later, after staying up alone most of the night. During the early stages of his illness, a patient may have many somatic complaints, variously diagnosed as fatigue, nervousness, neurosis, psychosomatic disease, or laziness. They are often treated for a year or more before the correct diagnosis is made. Later, many simple schizophrenics turn into tramps, hoboes, or beatniks. They become increasingly shallow in their emotional responses and are quite content to drift aimlessly through life as long as they are left alone.

Although the patients appear to be indifferent to

their environment, they may react with sudden rages to persistent nagging by members of their family. The immediate reason for admission of a simple schizophrenic to a hospital is often an outburst of violence directed against his mother for a very trivial reason. Further questioning invariably brings out the fact that the parents had been greatly upset over the patient's neglect of his personal appearance and his peculiar way of life and had many times admonished him, sometimes with threats, to conduct himself in a more acceptable manner.

An unmarried man, 27 years old, was brought to the mental hospital because he had on several occasions become violent toward his father. For a few weeks he had hallucinations and heard voices. The voices eventually ceased, but he then adopted a strange way of life. He would sit up all night, sleep all day, and become very angry when his father tried to get him out of bed. He did not shave or wash for weeks, smoked continuously, ate very irregularly, and drank enormous quantities of tea.

In the hospital he adjusted rapidly to the new environment and was found to be generally cooperative. He showed no marked abnormalities of mental state or behavior, except for his lack of concern for just about anything. He kept to himself as much as possible and conversed little with patients or staff. His personal hygiene had to be supervised by the nursing staff; otherwise he would quickly become dirty and very untidy.

Six years after his admission to the hospital, he is described as shiftless and careless, sullen and unreasonable. He lies on a couch all day long. Although many efforts have been made to get the patient to accept therapeutic work assignments, he refuses to consider any kind of regular occupation. In the summer he wanders about the hospital grounds or lies under a tree. In the winter he wanders through the tunnels connecting the various hospital buildings and is often seen stretched out for hours under the warm pipes that carry the steam through the tunnels.

Simple schizophrenics may resemble pathological personalities of the inadequate or schizoid type. But the distinguishing fact is that simple schizophrenia makes its appearance at some time during or after puberty and from then on, as a rule, goes on to pronounced deterioration; personality deviations usually commence earlier and then remain the same over the years.

Schizoaffective type. In the schizoaffective type of schizophrenic reaction there is a strong admixture of either depressive or euphoric affect with an otherwise definitely schizophrenic symptomatology. Schizoaffective patients may be deeply depressed, retarded, and suicidal; at the same time, they may express absurd delusions of persecution, complain of being controlled by outside forces, and have a distinct schizophrenic thought disorder. Or patients with similar schizophrenic symptoms may be euphoric, playful, distractible, and overactive. In the diagnosis of these cases the schizophrenic symptomatology takes precedence over the affective symptoms.

The prepsychotic personality of patients falling into the category of schizoaffective psychosis is not always typically schizoid. The prognosis of patients diagnosed as schizoaffective is generally better than that of other schizophrenics and generally worse than the prognosis of manic-depressives.

Latent reaction and residual state. Latent schizophrenia is diagnosed in those patients who may have a marked schizoid personality and who show occasional behavioral peculiarities or thought disorder, without consistently manifesting any clearly psychotic pathology. It is also known as borderline schizophrenia.

Residual schizophrenia is similar to latent schizophrenia. But latent schizophrenia is the stage prior to a schizophrenic breakdown, and residual schizophrenia is the state following the attack. Residual and latent schizophrenia are also known as ambulatory schizophrenia.

Childhood schizophrenia. Childhood schizophrenia is diagnosed when schizophrenia makes its appearance before puberty. Schizophrenia can occur in very young children and can even be diagnosed in infants. The prognosis for persons who develop schizophrenia before puberty or in their early teens is poor. Fortunately, this type is relatively rare.

Childhood schizophrenia presents somewhat different symptoms from schizophrenia in later life. It often manifests itself in young children as autism. Autistic children often show certain abnormalities of motor behavior and muscular tone in their 1st year of life and become arrested in their development during their 2nd or 3rd year. The most pronounced feature of infantile autism is a lack of normal communicative behavior. In spite of normal intelligence, autistic children may not learn to speak until they are 5 or 6 years old, and they never play normally with other children. They often do not respond normally to their mothers' affections or to any tenderness. They cannot clearly distinguish between animate and inanimate objects and consequently lack the normal childhood interest in pets and other animals. Their behavior is often repetitive and stereotyped.

Most schizophrenic children have a disturbed body image; they may, for instance, literally not know where their feet are. They may show poor motor coordination and many exhibit peculiar motor behavior, such as spinning and twirling. For Bender, schizophrenia in childhood is characterized primarily by a primitive plasticity, that is, uneven development caused by a maturational lag at an embryological level. According to Bender, much of the patterning of the schizophrenic child closely resembles that of the fetus. In childhood schizophrenia, homeostatic mechanisms are deranged to an even greater degree than in adult schizophrenia. In contrast to adult schizophrenics, the sleep of schizophrenic children is frequently disturbed. Older schizophrenic children who are not autistic are sometimes intellectually brilliant and precocious, but they fail to establish normal relationships with people and objects in the world around them.

Stephen was an alert baby but easily startled and perplexed. He started to talk at 10 months but did not walk until he was 21 months old. He had a hard time getting along with the

other children in kindergarten. The teacher thought his hearing was impaired. This was investigated and it was established that his hearing was normal. In school it quickly became evident that he could not attend regular classes because of his restless and peculiar behavior; he poked other children without any reason and kept repeating senseless phrases.

The boy went to special schools, but even there he failed to adjust. He easily lost his orientation and was liable to wander out onto the street and get lost. He was always careless in traffic. He tore his hair out compulsively. His parents were unable to control him. He compulsively had to touch people, often broke out into silly laughter and then became verbally aggressive without any apparent reason. He would hit his head against the wall, and occasionally he broke windows or tried to break the television set.

In spite of intensive psychiatric therapy and residential treatment in special schools, he made no progress and at the age of 15 was admitted to a mental hospital, where, over the last 5 years, he has received intensive courses of pharmacotherapy and electroconvulsive treatment as well as individual psychotherapy and milieu therapy. All these approaches have resulted only in insignificant improvement. He is now less impulsive and not quite so repetitive in his behavior, but he still pulls his hair out, tends to wander about aimlessly, repeats certain phrases stereotypically. He is much friendlier than he used to be, but he still fails to establish normal relationships with other people.

Late schizophrenia. Although schizophrenia is typically a disease of adolescence and young adulthood, it may, particularly in its paranoid form, make its first appearance in the 5th, 6th, or even 7th decade of life. Roth has described a group of late paraphrenias, functional psychoses that occur in aged individuals and in many ways resemble paranoid schizophrenia. German psychiatrists classify as late schizophrenics many psychotics who, in America, would be diagnosed as suffering from involutional psychosis.

Pseudoneurotic schizophrenia. In 1949 Hoch and Polatin described a clinical variety of schizophrenia to which they gave the name pseudoneurotic schizophrenia. Pseudoneurotic schizophrenics are, as the name implies, patients who present predominantly neurotic symptoms and who are usually treated for years as psychoneurotics. But on close and careful examination, they may reveal schizophrenic abnormalities of thinking and emotional reaction. Sometimes these are so well compensated that it is all but impossible to demonstrate them in clinical examinations, in psychological tests, or even in the history.

The pseudoneurotic schizophrenic is characterized by: (1) his lack of response to years of psychiatric treatment that would have produced improvement in most psychoneurotics, (2) a strange, all-pervading anxiety and a constant preoccupation with sexual problems. The diffuse pan-anxiety is probably the most specific diagnostic criterion.

Pseudoneurotic schizophrenics may have phobias, but these are not fixed and may amorphaously affect all areas of life over a period of time. Unlike patients suffering from anxiety neurosis, the pseudoneurotic schizophrenic's anxiety is always free-floating and hardly ever subsides, even temporarily.

The existence of this diagnostic category of schizophrenia has been contested by some psychiatrists, but

it is widely accepted on the North American continent. Its acceptance may have the practical value of re-orienting the therapeutic strategy in certain patients from unsuccessful psychotherapy to physical treatment methods, in particular, pharmacotherapy.

A 34-year-old single man has been hospitalized in a mental hospital for 1½ years. His main complaints are: "I feel panicky and very upset inside.... I am afraid something inside me might explode; and I might do something bad.... I feel depressed all the time.... I couldn't hold a job now if I did get one.... My head feels funny inside.... I always feel tense, sometimes I feel like two persons, sometimes I feel that everybody's against me...."

He was one of four children born into a family where all the members had fairly close relationships with each other and no major problems seemed to exist. Although he was always bright and considered to be the most talented of the four children, he failed his 3rd year of high school and blamed his difficulty on one teacher. He went to a special tutorial school and later obtained his B.S. with honors in chemistry at the age of 24. He got along well with his peers and participated actively in boxing, swimming, and singing.

In the 7 years after he graduated from college, he held at least nine different jobs. Several companies where he worked were sufficiently impressed with his ability to offer him special training. Various reasons were offered for the termination of his employment—not getting along with other staff, poor work, better prospects elsewhere, accidents to company cars, simply leaving the job, and personal difficulties. He was often unemployed. On one occasion he worked as an orderly in a hospital.

In spite of his apparently good social adjustment as a child, he says that he has never really enjoyed life and that he is always anxious with people. However, he has never manifested any clearly psychotic symptoms such as hallucinations, delusions, thought disorder, or irrational behavior.

At the age of 27 he felt acutely ill for the first time, following an episode of intense petting with his girl friend. "I was afraid of exploding.... afraid of doing something awful. Just generally tense." He was treated for a few weeks at a psychiatric clinic. Then he went to another city and worked for a short time but soon had to return home and to the psychiatric clinic. He now complained of a pulling sensation in the left side of his head.

Since then he has had 2 years of intensive psychotherapy, several courses of continuous sleep treatment, somnolent insulin therapy, several courses of electroconvulsive treatment, and prolonged treatment with a variety of minor and major tranquilizers.

He is now under close observation because of repeated suicidal threats and a few superficial suicidal attempts. He is convinced that he has some physical brain disease that is responsible for his constant tension, and he insists that some neurosurgery should be done to correct this. (Repeated neurological investigations have not revealed any lesion.) His spontaneous activity consists solely in reading the paper and watching television. He says he is too anxious to remain in any occupational setting for longer than a few days, after which he either asks for a new assignment or claims he is too weak to work at all.

Onciroid states. Oneiroid states in schizophrenic patients were first described by Mayer-Gross. In the oneiroid state the patient feels and behaves as though he is in a dream. (*Oneiros* is the Greek word for dream.) He may be deeply perplexed and not fully oriented in time and place. During this state of clouded consciousness, he may experience feelings of

ecstasy and rapidly shifting hallucinated scenes. Illusionary distortions of his perceptual processes, including disturbances of time perception, are common, and the symptomatic picture may resemble that of an hysterical twilight state. It is during such oneiroid reactions that the observer can most clearly observe the schizophrenic's peculiar "double bookkeeping," as Bleuler has called it. Here, the patient may be convinced that he is travelling through space on a satellite and, at the same time, conscientiously follow the regular hospital routine. The oneiroid schizophrenic will acknowledge everyday realities but will give priority to his world of hallucinatory and delusional experiences, whereas the normal person with a vivid fantasy life will always give priority to contingencies of reality. Oneiroid states are usually limited in duration and occur most frequently in acute schizophrenic breakdowns.

A 35-year-old married man was treated in a psychiatric hospital for an acute schizophrenic breakdown, from which he recovered in 2 months. Later he gave the following description of his experiences: "I had a horrible waking nightmare. I saw a large figure of a crude Stone Age man. It seemed to be a spirit figure. This frightened me, and I got out of bed and ran. As I got to the figure, I passed out. I found myself floating in the air in a spiritual body. I was terrified. In the morning I found myself at the foot of a stairway with no idea how I had gotten there. Then new very strange visions appeared. I had always had a very good imagination and an excellent talent to build pictures in my mind. Now I found life was changed completely. Before, it had been full of beauty and color. Now it was dull and uninteresting. Dreams were all nightmares. They were all about murder, suicide, and similar things. I found I could forecast the future and had many spiritual experiences. The impossible had become commonplace in my life. I was sure that any thought I had would affect somebody."

After a 20-year-old woman, a college student, had recovered from her schizophrenic breakdown, she wrote the following description of her experiences during the oneiroid phase:

This is not how I remember it. The road has changed. It is twisted and it used to be straight. Nothing is constant—all is in motion. The trees are moving. They do not remain at rest. How is it my mother does not bump into the trees that are moving? I follow my mother. I am afraid, but I follow. I have to share my strange thoughts with someone. We are sitting on a bench. The bench seems low. It, too, has moved. "The bench is low," I say, "Yes," says my mother. "This isn't how it used to be. How come there are no people around? There are usually lots of people and it is Sunday and there are no people. This is strange." All these strange questions irritate my mother who then says she must be going soon. While I continue thinking I'm in a kind of nowhere....

There are no days; no nights; sometimes it is darker than other times—that's all. It is never quite black, just dark gray. There is no such thing as time—there is only eternity. There is no such thing as death—nor heaven and hell—there is only a timeless—hateful—spaceless—worsening of things. You can never go forward; you must always regress into this horrific mess....

The outside was moving rather swiftly, everything seemed topsy-turvy—things were flying about. It was very strange. I wanted to get back to the quiet very badly but when I got back I couldn't remember where anything was (e.g. the bathroom)....

Suicide and Homicide

Suicide. Suicide in schizophrenia is a danger that must never be forgotten. More schizophrenics than manic-depressives commit suicide, despite the fact that the risk of suicide is relatively greater among manic-depressives. A schizophrenic may commit suicide because he is deeply depressed, for instance, during a schizoaffective reaction. Or he may kill himself simply in response to relentless commands he is receiving from his hallucinatory voices. One schizophrenic who had jumped to the street from a third floor balcony sustained several fractures but lived to tell us that for many days a man's voice had told him persistently to jump out of a window. He did not want to die, and he resisted the voice as long as he could, but he finally had to yield to its demands.

Some chronic schizophrenics have unpredictable suicidal impulses during brief spells of dejection. In a large mental hospital one or two chronic schizophrenics a year will make serious—and often successful—attempts at suicide. In many cases the psychiatrist and the nurses who had known the patient for a long time are unable, in retrospect, to recognize any change in his condition that might have been considered a warning of the impending tragedy.

Probably the greatest number of schizophrenic suicides occurs among those suffering from incipient schizophrenia. Sometimes, when the disease is in an early stage of development, even the victim's family and best friends have virtually no inkling of the terrible problem with which the patient is grappling. Many of the unexplained suicides among students on a university campus are probably committed by young persons who have become aware of a malignant, insidious process that threatens to destroy their minds. Rather than seek psychiatric treatment or confide feelings of uncontrollable disintegration to their friends, they choose to end their lives.

The following is an example of an unpredictable suicide in a schizophrenic who had been responding to psychiatric treatment:

The patient had been an autistic child and did not speak until he was 7 years old. He had responded well to psychiatric treatment, and at age 13 his I.Q. was reported as 122. At age 17, he became violent toward his parents, shaved all his hair off, and made such statements as, "I like bank robbers knocking people unconscious" and "I think tough gangs are funny because they beat down people." While saying this, he laughed loudly. He was admitted to a mental hospital, where he responded with definite improvement to pharmacotherapy and psychotherapy, and he went home regularly for weekends.

He left various notes on his desk before committing suicide. Among these notes was an 8-page list giving 211 "inexcusable mistakes throughout my life." Each one was dated, for example, "1952, 2nd of November: throwing up in my friend's house on a shoe-box. 1953, 17th August: accidentally wearing a watch that wasn't water-proof in the bath-tub. 1956, 23rd of September: slamming back-door of Meteor after getting in."

He then proceeded in his notes to give "the causes of the mistakes": "Montreal having a mountain; I have a receding hair-line; my height since I was nine years old; Canada having

two languages..." He also wrote: "My feeling of tension since 1962 is getting worse most of the time. I planned the date of my death without the slightest trace of emotion..."

The boy hanged himself at age 18 in the family garage. An experienced psychiatrist who had repeatedly interviewed him noted no signs of depression only a week before.

Homicide. One of the most serious problems a psychiatrist may have to face is the assessment of the possibility or probability that one of his patients may commit homicide. This dilemma has few parallels in medicine because it involves the life of other healthy persons as well as the welfare of his own patient.

This writer, in reviewing nearly 25 years of psychiatric practice devoted primarily to the treatment of psychotics, has found that 25 persons have been killed by psychotic patients he had either known or treated personally. This averages to 1 healthy person per year killed by psychotics, most of whom were schizophrenics. Even if one keeps in mind that some psychotics killed 2 or 3 victims and that the population from which this sample of homicidal psychotics was drawn numbers about 10,000 psychotic patients, this figure is still frighteningly high.

Unfortunately, it is exceedingly difficult to prevent most schizophrenic homicides, since there is usually no clear warning. Most of them come as a horrible surprise. Patients who are known to be paranoid with homicidal tendencies are not allowed to move about freely as long as they retain their delusions and their aggressive tension. But, like the patient who hanged himself without previously manifesting any observable tension or depression, the homicidal schizophrenic patient may appear to be relaxed, even apathetic, and within a day or two kill somebody without any clear warning.

A schizophrenic man who had been going home on weekends for many months was told by his sister that she would not ask for permission any more to take him out of the hospital if he would not do his part with the housework in the future, for instance, help with the dishes. On the next weekend visit, the patient killed his sister and mother. He had shown no signs of disturbance whatsoever during the preceding week, had been sleeping well, and had been attending occupational therapy classes as usual. If anything, he had appeared somewhat more indifferent than usual.

A 19-year-old boy who had been discharged from a mental hospital in what appeared to be a residual state of chronic schizophrenia of the undifferentiated type stabbed his father to death when the latter, during a state of intoxication, told the patient that he was too much of a bother around the house and that he might as well return to the hospital.

Another schizophrenic, whose condition had not yet been diagnosed, complained to a general practitioner about various physical ailments. When the physician finally told him that he should not come anymore because there was nothing else he could do for him, the patient quietly left the office but returned a few hours later and killed the doctor.

Rejection. A careful analysis of these unpredictable suicides and homicides leads one to conclude that the most significant single factor in many of them was a traumatic experience of rejection. The schizophrenic's pathological sensitivity makes him extraordinarily vul-

nerable to all common life stresses. Rejection, particularly by members of his own family, seems to be more traumatic to him than most other stresses. The act of rejection may seem very trivial and is often not deliberate on the part of those who reject the patient. They are, in fact, practically never aware of it, and the patient may not show any immediate reaction to the rejection at the time.

The schizophrenic patient who committed suicide in his family's garage killed himself during a weekend when his parents had gone away for a 10-day trip. They had at first promised to take him along. Then they reversed their decision and went alone. The patient was interviewed about the effects of this particular disappointment and did not reveal any particular reaction to it. In retrospect, however, it appears that his parents' implied rejection of him may have been at least the precipitating factor for his suicide.

It may be significant that three of the schizophrenic patients who committed homicide harbored the delusion that their parents were foster parents rather than real parents. This delusion in itself seems to reflect a deep-seated feeling of rejection by the parents.

Changing Symptoms

Do schizophrenic patients behave in the same way all over the world? Do schizophrenic symptoms change as times change? These interesting questions are being studied by the new discipline of comparative or transcultural psychiatry.

In 1904 Kraepelin studied the manifestations of dementia praecox in a mental hospital in Java and came to the conclusion that the incidence of schizophrenia was as high in Java as it was in Europe. But its clinical manifestations were distinctly different. The Javanese natives showed fewer paranoid symptoms and had fewer auditory hallucinations. Kraepelin attributed this finding to cultural differences and to the fact that at that time the abstract thinking of most natives in Java was still relatively undeveloped.

Today it is generally accepted that cultural influences determine to a significant extent the actual manifestations of a mental illness. Cultural differences are distributed in two dimensions: geographical and historical.

Geographical differences. In some European countries, the catatonic form of schizophrenia is the most common form; in the United States, paranoid schizophrenic reactions are the most common. In Brazil and in Africa there is a remarkably low incidence of the paranoid form of schizophrenia and a much higher incidence of hebephrenic schizophrenia than in Europe and the United States. In general, it appears that paranoid reactions prevail among schizophrenics from more differentiated cultural spheres, and catatonic reactions occur more frequently in less developed cultures.

Murphy et al. reported that visual and tactile hallucinations seem to be more common among the

schizophrenics of the Near East and Africa. The same authors found that religious delusions are noted most frequently among Christians, less frequently among Buddhists, and least frequently among Hindus. Catatonic mannerisms and catatonic stupor are more often seen in rural populations than among urban dwellers. Ideas of grandeur and delusions about the end of the world also occur more frequently in the rural population, particularly among schizophrenics belonging to the Christian faith. These studies established that hebephrenic reactions are comparatively common in Japan and Okinawa and that the simple type of schizophrenia is more common in Asia than in the European-American sphere. Catatonic negativism and catatonic stereotypies are more prevalent in India and South Africa than in European and American countries.

Spitzer compared hospitalized schizophrenic patients in Kentucky with matched samples of schizophrenics in New York. He observed that schizophrenics in Kentucky were more likely to present symptoms of decreased communication, denial of illness, and impaired grooming; schizophrenics in New York clearly showed more affective symptoms than the less sophisticated sample of schizophrenics in Kentucky.

Historical differences. Recent studies have established clearly that the changing *Zeitgeist*—the historical changes in philosophical, religious, technical, moral, and political value systems—has a significant influence on the relative frequency of individual schizophrenic symptoms. Several investigators have observed, for example, that the catatonic form of schizophrenia is gradually becoming less frequent in the United States.

Lenz analyzed the case records of 430 patients who had been hospitalized in Austria during the period between 1856 and 1955. His findings show a decrease of religious guilt feelings in schizophrenia in the second half of this period, although the total proportion of guilt feelings, including those toward other persons, had not changed. The frequency of hypochondriacal ideas and preoccupations did not change throughout the whole period and remained quite stable, at about 25 per cent, among the schizophrenics.

On the other hand, schizophrenics today are definitely less aggressive than they were 50 years ago. It is not clear whether this reduced aggression reflects a true change in the character of schizophrenia or whether it is the result of more effective, early therapeutic control methods. Visual hallucinations decreased, and auditory hallucinations increased significantly in the last half of the period. Delusions of grandeur increased for a while during the First World War and again during the Second World War but have been in a general decline over the years. Delusions of witchcraft and other magic influences have become less frequent, and ideas about being hypnotized or being influenced by radiation and electricity

have definitely increased in frequency in recent years. In the same study it appeared that experiences of being passively influenced by anonymous agencies—"They are reading my thoughts"—have become more frequent in recent times, but delusions of having a mission or being a martyr are less frequent today. In general, there is apparently a definite tendency for the contents of delusions to become more realistic, sober, plausible, and anonymous.

In a similar study on schizophrenics in Finland, Achte compared the psychopathology of 100 schizophrenics in the years 1900, 1930, and 1960. He found that negativism, mutism, and stupor had shown a marked decrease in every 30-year period, from 22 to 2 per cent in the 60 years covered by the study. Religious delusions decreased from 20 to 10 per cent. But physical and technical delusions increased from 12 to 31 per cent. Achte also found an increase of delusions involving telepathy and hypnosis. The same investigator examined 200 schizophrenic case histories between 1933 and 1955. He found that the paranoid form of schizophrenia had significantly increased and the catatonic form decreased during these 22 years, but the percentage of hebephrenic reactions had remained the same.

Examining a group of recently hospitalized schizophrenics in 1942 and a comparable sample in 1962 in the Montreal area, Lehmann et al. observed that the incidence of delusions and hallucinations had not changed, but suicidal preoccupation had significantly decreased in the later group.

Most researchers agree that delusions of being controlled or being poisoned have not been influenced by historical or cultural changes. They seem to represent a stable core of schizophrenic pathology that remains the same in various parts of the world and in different periods of time.

Even if not all of these findings are valid, there seems to be little doubt about certain general trends. These would include a decrease of catatonic reactions and an increase of paranoid reactions among schizophrenics belonging to more sophisticated cultural groups, a decrease of supernatural delusions and an increase of delusions involving modern technical and scientific apparatus. In the Middle Ages delusions of persecution were invariably attributed to witchcraft and the devil; in the 19th century they involved magnetism and mesmerism; later they centered on hypnosis and telepathy; still later, x-rays, radio, and radar came into the picture, followed by television and finally, atomic rays from artificial satellites. The thread linking all of them is that they involve mysterious, invisible forces operating from a distance.

Diagnosis

There are no objective criteria for the diagnosis of schizophrenia. Few psychiatrists anywhere would disagree on the diagnosis of severely regressed, chronic, or very typical acute schizophrenics. But there are

many psychotic patients in whom there remains at least some doubt about the diagnosis. Certain schools of thought, theoretical or philosophical biases, and even diagnostic fashions may have an important influence on the diagnosis. European psychiatrists accuse their North American colleagues of making the diagnosis of schizophrenia too frequently. They have even referred to this penchant as "schizophrenomania." Epidemiologists are puzzled by the fact that in the United States the incidence of manic-depressive psychosis has greatly decreased in the last 20 years, but it does not seem to have changed significantly in the rest of the world. Does this development reflect the influence of some unknown factors that have brought about a true decrease of manic-depressive psychosis in the United States? Or is it because in recent years it has become customary in the United States, unlike most other countries, to diagnose schizophrenia more frequently than it was diagnosed previously?

It cannot be denied that there is in North America a greater tendency to diagnose schizophrenia than in other countries, which could easily explain the decrease in numbers diagnosed as manic-depressive. This tendency may, in turn, be explained by the fact that many psychiatrists take it for granted that a patient who is hallucinating or expresses paranoid delusions must be schizophrenic if no organic brain disease can be detected. Yet, the presence of delusions and hallucinations confirms the diagnosis only of psychosis, not of schizophrenia. These symptoms indicate a serious loss of contact with reality, a principal criterion for the diagnosis of a psychotic condition that may or may not be schizophrenic. However, it is well known that between 15 and 25 per cent of manic-depressive patients may have hallucinations or delusions. Weibrecht has recently reviewed the confusing situation relative to the psychopathology of schizophrenia and depression and has drawn attention to the fact that symptoms of definite schizophrenic coloring today quite frequently occur in cyclothymic depressions. There are other nonschizophrenic psychiatric conditions—such as paranoid states, involutional psychoses, hysterical twilight states—where delusions and hallucinations may also occur.

To diagnose schizophrenia simply on the presence of delusions and hallucinations is like making the diagnosis of a coronary occlusion only on the basis of pain in the chest or the diagnosis of typhoid fever only on the presence of a sustained pyrexia. Single symptoms should certainly *suggest* the diagnosis of conditions in which such symptoms frequently occur. But unless there are specific, conclusive tests for the existence of certain disease processes, a final differential diagnosis must be based on the whole clinical picture.

Unfortunately, the diagnosis of schizophrenia cannot be made solely on the basis of observation or reasoning or measurement. It still involves a careful and comprehensive clinical evaluation. Such an evaluation must take into account the presence or absence of cer-

tain schizophrenic key symptoms, the patient's prepsychotic personality, the physical findings, the genetic family history, the various aspects a good, clinical anamnesis might reveal about the natural history of the disease and any possible precipitating factors.

Key symptoms. The presence of some key symptoms for schizophrenia as described by Bleuler and Schneider—for instance, blunting of emotional responses or a strikingly inappropriate emotional response—would weigh heavily in favor of a diagnosis of schizophrenia. But what is "emotional blunting," and what is an "inappropriate emotional reaction"? Is the embarrassed adolescent's sheepish or defying smile an inappropriate emotional reaction, for example? It requires considerable clinical experience to be certain about the presence of such symptoms.

Perceptual disorders. What other factors can serve as the basis for a diagnosis of schizophrenia? Sensory and perceptual disorders, such as hallucinations, may give good diagnostic clues. However, not all hallucinations indicate a schizophrenia. There are very important qualifications regarding the modality, the time, and the content of the hallucination. Experiences of being controlled by outside forces or of having strange, continuous, somatic (cenesthetic) hallucinations or auditory hallucinations, particularly if the voices are coming from God or the devil, may indeed support a diagnosis of schizophrenia. Perceptual distortions of time or objects in space point toward a diagnosis of schizophrenia, but only if they have been present at least several days; otherwise, they may well be of toxic origin. The same time factor applies to the symptoms of loss of ego boundaries, the experience of being fused with the universe and of having one's thoughts spread to others.

Loosening of associations. The loosening of associations—the specific thought disorder of the schizophrenic—is, perhaps, one of the most valuable diagnostic criteria. But a good knowledge of psychopathology is required to be sure of its presence and to avoid confusing it with other forms of disturbed thinking, such as manic flight of ideas, confused disintegration of thought processes, and impaired reasoning due to fatigue or distraction. It is obviously not sufficient to ask a patient the meaning of a proverb and then, on the basis of one's personal impression, declare that the patient has a pronounced schizophrenic thinking disturbance.

Delusions. The presence of delusions provides strong presumptive evidence for schizophrenia if these delusions have strange, magical, esoteric, or bizarre contents. A person who is convinced that he is deliberately discriminated against by his foreman at the factory or that his wife is running around with other men, or even that his wife is trying to poison him may have paranoid delusions, but they are not necessarily due to schizophrenia. On the other hand, a man who is convinced that he is the victim of a Pentagon-directed plot to destroy his brain by special death rays beamed

at him from space satellites or that he is the Virgin Mary expresses delusions that, by their very bizarre character, point definitely in the direction of schizophrenia.

Bizarre behavior. The patient's behavior may furnish significant clues for the diagnosis of schizophrenia. Bizarre postures and grimacing certainly are characteristic of schizophrenic conditions, but what constitutes a bizarre posture is not always easy to establish unequivocally. Religious rituals and special praying positions or rock-and-roll dancing or ataxia with which the observer is not familiar might be called bizarre. On the other hand, true catalepsy may be almost pathognomonic of schizophrenia. A stupor is highly suggestive of catatonic schizophrenia, but hysteria or a depressive stupor must be carefully ruled out in the differential diagnosis.

Deterioration of social habits, even involving smearing of feces, is certainly not sufficient grounds for the diagnosis of schizophrenia. Such deterioration can occur in various toxic and organic psychoses, temporarily in hysterical twilight states, and even at the peak of a manic attack in manic-depressives.

Pronounced social withdrawal also occurs under many conditions ranging from simple sulking to anxiety and depression. Sustained passivity and lack of spontaneity should suggest the diagnosis of schizophrenia only if organic and depressive conditions can definitely be ruled out.

Stereotypies and verbigeration strongly suggest schizophrenia. But they occur almost exclusively in chronic conditions. Frequent and lengthy staring into a mirror and other odd mannerisms are also highly suggestive of a diagnosis of schizophrenia.

Praecox feeling. Rümke insists that the only valid diagnostic criterion is the "praecox feeling." This feeling consists in an intuitive experience by the examiner that determines whether or not it is possible to empathize with the patient. Rümke believes that only those patients whose emotional distance makes it impossible to establish an empathic rapport should be diagnosed as schizophrenic; all other conditions should be regarded as schizophreniform. The acceptability of Rümke's approach was demonstrated in a study of 1,000 psychiatrists, in which 54 per cent declared that the praecox feeling was a reliable criterion for making a diagnosis of schizophrenia.

However, at this stage of our knowledge it would appear to be unwise to substitute a single subjective approach for a whole range of other traditional, clinical skills. It would be equally unwise to follow a purely actuarial approach to the question of diagnosis by relying entirely on factor analysis and cluster analysis of rating scale items or test results.

Prepsychotic personality. A clinical evaluation must always consider the patient's prepsychotic personality. The typical but not invariable history is that of a schizoid personality: quiet, passive, with few friends as a child; day-dreaming, introverted, and

shut in as an adolescent and adult. The child is often reported as having been especially "good" because he was always obedient and never in any mischief. In school he was good in spelling but poor in arithmetic. He made few friends as a child, and his deficient friendship pattern was particularly noticeable in adolescence. The typical schizoid adolescent has few dates, does not learn to dance, and, as a rule, has no close boy friends or girl friends. He is not interested in petting or other heterosexual activities but is often disturbed about masturbation. He avoids all competitive sports, but he likes to go to the movies, watch television, or listen to hi-fi music. He may be an avid reader of books on philosophy and psychology.

The work history of many schizophrenics is characteristic. They may have had many different jobs but held none for long. It is usually difficult to ascertain why they did not stay longer in any position. The reasons given are usually vague, and neither the patient nor, in many cases, the employer can explain exactly just what happened. But it appears that everybody—the patient, his employer, the people with whom he worked—were all somehow uncomfortable while he was working. Perhaps the patient was careless in his work, came in late, and made frequent mistakes. He may have made an unfavorable impression at times when there was not much to do by failing to create at least the appearance of being busy. Or maybe he simply could not stand the presence of the people with whom he had to work; they irritated him or made him anxious or suspicious. It is not unusual in these cases for a patient to change jobs 10 or more times in 1 year.

Origin and outcome. Two of the principal criteria that Kraepelin established for his diagnosis of dementia praecox—its endogenous origin and the outcome in deterioration—are still valid, although limited in their applicability. An endogenous origin may be obscured if stressful events precipitated, but did not cause, the final breakdown. In most cases a psychiatrist must make a diagnosis before the patient has deteriorated.

The concept of schizophreniform psychoses that Langfeldt introduced—splitting schizophrenia into schizophreniform psychoses and true process schizophrenia—seems to amount to a return to Kraepelin's old dementia praecox concept. It is certainly not justified to change the diagnosis of a patient diagnosed as schizophrenic simply because he recovered from his symptoms after 2 or 3 weeks of therapy. Even the 3-day schizophrenias—acute, psychotic breakdowns with schizophrenic symptoms that remit in a few days—may well be benign but *true* forms of schizophrenia rather than pseudoschizophrenic reactions, as they are sometimes called.

Rado sees schizophrenia as a breakdown of adaptive struggles and interprets the clinical forms of schizophrenia as developmental stages of schizotypal behavior: compensated, decompensated, disintegrated, and deteriorated. In compensated schizotypal behav-

ior, patients may go through life without a breakdown. Decompensated schizotypal behavior is similar to the clinical picture of pseudoneurotic schizophrenia. Disintegrated schizotypal behavior manifests itself as an overt, schizophrenic psychosis. Finally, deteriorated schizotypal behavior is marked by a progressive cessation of function and an almost complete withdrawal from the adaptive task.

Differential diagnosis. A clinical evaluation for the purpose of establishing a diagnosis should take into account four major parameters: (1) the patient's prepsychotic personality, (2) the endogenous origin, (3) the typicality of the psychotic symptoms, and (4) the outcome.

For instance, in a patient whose personality structure has not been schizoid and whose breakdown occurred in close relation to some traumatic experience, the symptomatology should be very typical if a diagnosis of schizophrenia is to be made. Since the outcome of the psychosis is not yet known and the prepsychotic personality and endogenous origin are not clearly established, schizophrenic symptoms must be particularly convincing.

On the other hand, if the history is that of a typical shut in personality, in whom the psychotic breakdown occurred without any preceding stress situation, the symptoms would not have to be extremely characteristic in order to defend a diagnosis of schizophrenia. Of course, if there is already evidence of personality deterioration after the acute symptoms have subsided and a year or two have passed, the outcome would be the overriding parameter in the diagnostic evaluation. A less skilled observer may be confused by the presence of a number of common but nontypical symptoms accompanying schizophrenic breakdowns.

Hysterical symptoms, for example, are not uncommon in acute schizophrenic breakdowns; thus the presence of hysterical dissociative or even conversion symptoms does not rule out a diagnosis of schizophrenia. Every schizophrenic breakdown is preceded by a period of marked tension and anxiety, which may last only a few days or may extend over many months. During the acute and subacute stages of a schizophrenic attack, anxiety and depression may color the clinical picture significantly, again without excluding the overruling diagnosis of schizophrenia, which in such cases has not yet diminished the patient's emotional reaction to the onslaught of the psychotic attack. Obsessive symptoms are commonly observed in schizophrenic conditions and an obsessive-compulsive clinical picture can develop into schizophrenia.

The differential diagnosis between schizophrenia and manic-depressive psychosis should, as a rule, not present many difficulties. The behavior of an excited catatonic patient is directed primarily by his own qualitatively disordered mental processes. His actions are unpredictable and appear senseless, his affect is difficult to understand, and his verbal productions may be irrational and incoherent. A manic patient, on

the other hand, is always distractible, and most of his actions are determined by his immediate environment. His activity resembles that of an excessively busy person, rushing from one superficial job to another. His affect is clearly one of playful euphoria or angry irritability, but always outgoing and expansive. His verbal productions are accelerated and increased in number, and they reveal a quantitative disorder of association processes rather than the intrinsic, qualitative thought disorder of the schizophrenic.

Similarly, depressive conditions should never be diagnosed as schizophrenic unless there are also some unmistakably schizophrenic symptoms present. To illustrate, in schizoaffective reactions, which resemble manic-depressive conditions, the presence of clearly schizophrenic symptoms, such as schizophrenic thought disorder, places these reactions in the diagnostic category of schizophrenia.

The author's own observations do not confirm the widely accepted psychiatric teaching that a diagnosis of manic-depressive psychosis is often changed later to one of schizophrenia but that the opposite never occurs. During more than two decades at a psychiatric hospital serving the entire English-speaking population of the bilingual Canadian province of Quebec, he has many times changed an early diagnosis of schizophrenia made during the first one or two attacks into a diagnosis of manic-depressive psychosis during subsequent psychotic breakdowns.

Any psychiatric disorder that occurs during adolescence assumes a certain schizophrenic coloration, since many of the features characteristic of nonschizophrenic adolescent turbulence—exaltation, intense preoccupation with abstract ideas, unpredictable variations of mood, day-dreaming, introspection, shyness—are often seen in schizophrenia. Therefore, it is not unusual to misdiagnose a manic or depressive phase of manic-depressive psychosis as schizophrenia if the patient's first attack occurs in late adolescence. Also, the usual rule that manic-depressive psychosis does not occur at this early an age simply does not always hold true. Later recurrences of this mental disease may cease to display symptoms resembling schizophrenia, and the correct diagnosis can then be made.

Finally, the patient's body build, prepsychotic personality, and family genetics are also helpful in making a differential diagnosis.

Psychological Tests

Psychological tests may serve as valuable aids in the diagnosis of schizophrenia, although they can hardly ever establish this diagnosis by themselves, that is, divorced from the clinical findings. There are no psychological tests for schizophrenia comparable to the definitive biological or immunological tests for pregnancy or syphilis. There are only psychological tests which are more or less *compatible* with a diagnosis of schizophrenia, making the diagnosis more or less probable.

It must be remembered that the clinical psychologist uses his test instruments to arrive at diagnostic classifications which were originally derived from purely clinical observation. The clinical psychologist's tests differ from clinical observation by the fact that, unlike the psychiatrist's observation and interview, the method of test administration is uniform and the final evaluation of the test findings is based on statistical standardization. At least, this is true for psychometric test instruments. Projective tests are much less objective and, therefore, also less reliable, although they may provide more valuable information than psychometric tests.

The specific diagnosis of schizophrenia is made by the clinical psychologist on the basis of a composite of test results. Certain specific patterns of psychological dysfunction carry a high diagnostic index value for schizophrenia. Some single components of the over-all test pattern may be almost pathognomonic for schizophrenia, e.g., bizarre confabulations, and others may only have some supportive value in a general pattern of malfunctioning, e.g., lack of concentration.

In most clinical centers certain psychological test batteries are routinely employed to indicate, confirm, or rule out a diagnosis of schizophrenia. These test batteries are usually composed of projective tests as well as psychometric tests. The most frequently employed projective tests are the Rorschach Test, some drawing tests, and the Thematic Apperception Test (TAT). The most commonly employed psychometric tests are The Wechsler Adult Intelligence Scale (WAIS) and some tests that probe concept formation and the organization of thought processes.

The special value of projective test procedures lies in the richness of dynamic material that they often provide, thus giving the clinician considerable insight into the associations, imagery, preoccupations, conflicts, and defense mechanisms of the tested person. Experimental psychologists criticize projective techniques because of their low reliability and the highly subjective methods employed in their interpretation. The TAT, in particular, seems to be not one, but many instruments. Its scoring is less well standardized than the scoring of the Rorschach Test, and, therefore, the TAT is, at the present time, probably more a research instrument than a diagnostic tool.

The diagnostic validity of the Rorschach Test is better established. However, it has been found that the diagnostic validity for schizophrenia established with the Rorschach in one sample of patients can sometimes not be reconfirmed in a different sample at another place. Content analysis of the Rorschach seems to give more reliable findings than diagnostic evaluation based on the formal structural "profile" of perceptual, conceptual, and organizational characteristics. Attempts to derive a diagnosis from the presence or absence of certain "signs" in the Rorschach data have definitely been unsuccessful, and prediction of overt behaviour based on Rorschach data has also met with

only very limited success. The most valid and reliable results are obtained by experienced clinical psychologists who are basing their diagnostic conclusions more on a global, clinical approach to the Rorschach Test findings than on a structural analysis of the data.

For a more detailed discussion of the theory and practice of clinical psychological testing, the reader is referred to the extensive literature on these subjects and also to Section 12.1 in this text. However, for the psychiatrist who simply wishes to understand on what diagnostic findings a clinical psychologist bases his diagnostic impressions of schizophrenia, some of the more significant test findings in schizophrenia will be listed here.

Rorschach Test. In the Rorschach Test the most specific, almost pathognomonic findings are confabulation and contamination responses; e.g., a schizophrenic patient gave the response "terrestrial sex" to one of the Rorschach ink blots where he had perceived one part of the blot as a penis and the rest as a geographical map. But such perceptual-conceptual incongruities are not observed frequently. The schizophrenic's thought disorder as well as his perceptual disturbances are more commonly reflected in poorly perceived form responses and in a perseverating repetition of the same concept. There is usually also a lack of human movement responses and an inability to integrate colors effectively into percepts with the result that the colored objects which are perceived by the schizophrenic tend to have a crude and raw quality, e.g., "a bloody thigh," "a pile of feces," "fire and explosion." The schizophrenic's deficiency in social adaptation is often reflected in the unusually small number of so-called popular responses he gives to the blots. These are responses which are quite frequently evoked by the ink blots in normal individuals—e.g., "two men bowing to each other" in the third card, "a bat" in the fifth card, "two animals" in the eighth card—but which the schizophrenic patient is unable to see.

Thematic Apperception Test. The TAT, although it does not contribute significantly to the diagnosis of schizophrenia, can, nevertheless, provide important information about the specific dynamics involved in individual schizophrenic symptoms, and the test findings might thus give valuable aid to the planning of a therapeutic strategy for the individual schizophrenic patient. The stories the patient invents might, for instance, reflect his disturbed relationship with his mother or his pervasive fears of persecution.

Drawing tests. The two most commonly used projective drawing tests are the House-Tree-Person (HTP) and the Draw-a-Person Test (DAP). In the first test the subject is asked to draw a house, a tree, and a person; in the DAP he is only asked to draw a person. General expansive and regressive trends are quite regularly noted in the representative drawings of schizophrenics. More specific for schizophrenia are the gross distortions of the body image appearing in the drawings of persons, the grotesque deformities of ob-

jects, the manneristic style of drawing, the fragmentation or bleak emptiness which often characterize the graphic productions of schizophrenic individuals. These features may be so typical that an experienced clinician may occasionally be able to make an accurate diagnosis of schizophrenia after seeing only one or two of such drawings by a patient. However, it is hardly necessary to point out that such diagnostic stunts, based on one or two single manifestations of pathology, are neither a practical nor a reliable method of arriving at a clinical diagnosis in psychiatry.

Wechsler Adult Intelligence Scale. The WAIS is most suggestive of schizophrenia if there is a pronounced scattering of the various subtest scores. Such a scattering reflects pathological variability and unevenness of intellectual functioning. Quite regularly, the verbal I.Q. of schizophrenics is considerably higher than the performance I.Q., and within the verbal part of the test there are configurations which are highly suggestive of schizophrenia, e.g., a low similarity score associated with a high vocabulary and information score. This configuration reflects an imbalance between a well preserved memory function and impaired abstract reasoning. Schizophrenics usually score low on the picture completion subtest. This subtest requires careful observation and concentration in order to discover certain details which have been omitted in the pictures of some familiar objects. An occasional finding in schizophrenia is the combination of a high similarity with a very low picture completion score. The digit span, which tests immediate memory, remains, as a rule, relatively intact in schizophrenia, at least more so than in acute anxiety states, organic psychoses, depressions, and manic states. Mental arithmetic, however, is characteristically poor in schizophrenics, another manifestation of impaired concentration in this disease. The picture arrangement score is low in schizophrenia, probably because of the schizophrenic's impaired social adaptation, since this subtest calls for the ordering in sequence of several pictures representing human activities.

Finally, there are now a number of standardized tests which can give quantitative information about disorders of conceptualization and overinclusive thought processes. These tests may require the patient to pick from a list of words those which denote things that are essential components of a wider concept, or they may present the patient with a number of objects which he is asked to classify into certain groups. Other tests in the same category require a sorting of cards into groups according to certain characteristics, such as color, shape, size, or other general qualities.

In summary, a diagnosis of schizophrenia is supported by psychological tests if these reflect unusual or bizarre perceptual and conceptual processes (Rorschach; TAT; drawing tests; WAIS, particularly the similarity subtests). Other typical findings are variability and an uneven scattering of test scores (WAIS) and disturbances of concept formation, in particular,

overinclusive and autistic thought processes (object sorting and concept formation tests).

Prognosis

It has been known since Kraepelin and Bleuler that the hebephrenic and simple types of schizophrenia have the poorest prognosis, that paranoid reactions have an intermediate prognosis, that acute catatonic reactions have the best prognosis, but that catatonic patients who go on to chronicity usually continue to regress and become markedly deteriorated.

Modern pharmacotherapy with neuroleptics has changed many of the old prognostic patterns. Today a paranoid schizophrenic's chances to make a good recovery are at least equal to those of an acute catatonic. Even hebephrenics nowadays often have good remissions after a few months of pharmacotherapy. The simple schizophrenic is still the least responsive to modern physical treatment methods.

The more acute the onset of a schizophrenic attack, the better are the chances for a good remission or complete recovery. If a precipitating event has clearly triggered the breakdown, the chances for a favorable outcome are also relatively better.

The younger a patient is at the onset of his schizophrenic psychosis, the worse is his prognosis, as a rule. Patients who break down in childhood or early puberty seldom recover completely. Married schizophrenics have a better prognosis than single, divorced, or widowed patients: the fact that they are married is evidence that interpersonal bonds may serve as a bridge for a return to the community.

A history of good social, sexual, and occupational adjustment prior to the breakdown also indicates a favorable prognosis. A patient who relates easily to people in his environment and who is capable of emotional warmth and natural emotional reactions has a good chance for reintegration. Conversely, sustained emotional withdrawal and aloofness or shallow and inappropriate affective responses are ominous prognostic signs.

The patient's family plays an important role in his prognosis. A number of studies in recent years have established the fact that most schizophrenics come from deeply disturbed families. Important questions to be answered before making a prognosis are: Is the patient accepted by his family? Is the family schizophrenogenic, with a domineering, overpossessive, and overprotective mother and a cold or ineffective father? Is the dynamic pattern of communication within the family adequate or does it produce double bind messages?

If the patient has a job waiting for him after he leaves the hospital, his prognosis is favorably influenced.

A new prognostic factor has emerged in the last few years: the patient's cooperation and degree of conscientiousness in following prescribed drug maintenance therapy. Many schizophrenic patients today

can be rendered symptom-free within a few weeks or months, but they can only be maintained in this condition with continued drug therapy after they have been discharged into the community. The more often a patient neglects to take his maintenance medication, the more likely he is to suffer a relapse, and the more likely he is to deteriorate and to develop finally a permanent personality defect.

The risk of personality deterioration increases with each schizophrenic relapse. Schizophrenic recoveries are often called remissions because many of the patients later relapse. Although they may remit again, there is with each schizophrenic attack a greater probability of some permanent personality damage. This risk of personality deterioration increases rapidly after the second relapse.

On the other hand, some schizophrenics have five or more psychotic attacks, usually of the catatonic type, without suffering any definite personality damage. Because of the increased risk of the development of a schizophrenic defect after each additional schizophrenic attack, today's therapeutic challenge is to use all available measures to prevent relapses.

Final Outcome

A schizophrenic patient's chances for a favorable outcome of his psychosis are today estimated to be about four to five times better than they were only 50 years ago. Emil Kraepelin reported in 1913 that nearly 13 per cent of his patients with dementia praecox recovered from their first attack, but most of these later relapsed. Altogether, only about 15 per cent ultimately had passable, social remissions, usually with slight to moderate personality damage.

A more optimistic picture emerged from an important study by Manfred Bleuler, the son of Eugen Bleuler, who had been the first to describe the clinical picture of schizophrenia. Manfred Bleuler's comprehensive study of relative frequencies of outcome for a large sample of schizophrenic patients was undertaken before the new neuroleptic agents came into widespread use. Thus, his findings would still understate the favorable prospects that now exist for the schizophrenic patient.

Today fully 40 to 50 per cent of patients who have suffered acute schizophrenic breakdowns can be discharged back into the community symptom-free within 6 months to a year. In all, 75 to 80 per cent will be able to go home and live reasonably successfully, despite certain symptoms or personality defects some of them may retain.

With follow-up therapy and maintenance drug treatment, only some 10 to 15 per cent of patients in remission will relapse within a year. This should be compared to about 35 to 40 per cent who would relapse during the same period without such follow-up treatment.

There are five possible outcomes for the schizophrenic patient: (1) full and permanent recovery, (2)

full remission with one or more future relapses, (3) social remission with personality defect, either capable of self-care and self-support or dependent on protection and supervision, (4) stable chronicity, and (5) deterioration to terminal stage.

Deterioration to a terminal stage. This vegetable-like existence is a rare phenomenon among schizophrenics who have become ill during the past 15 years. Modern physical and social treatment methods are in most cases successful in preventing at least the terminal stage of deterioration, which was the most probable outcome of schizophrenia in Kraepelin's time and which was probably due more to the ravages of institutionalization than to schizophrenia.

In the modern mental hospital, it is increasingly difficult to find patients who illustrate this terminal stage of schizophrenia. Almost all cases to be found with the symptoms and signs of extreme regression of behavior, affect, and ideation were admitted 20 or more years ago.

Stable chronicity. There are still many schizophrenics who, despite all intensive therapeutic efforts, remain in a state of stable chronicity, although they do not regress to a terminal stage of deterioration. Their psychotic symptoms may make it necessary to keep them hospitalized, or, if the symptoms are not severe, they may reside outside the mental hospital. But they will remain definitely incapacitated with signs and symptoms of active mental disease.

It is difficult to estimate how many schizophrenics today will end up in this category of stable chronicity. But under ideal therapeutic conditions the proportion almost certainly will not exceed 25 to 30 per cent. The remainder of the schizophrenic patients will either remit or recover.

Remission. The majority of schizophrenics today will emerge in the categories of social remission with personality defect or full remission with further relapses.

Schizophrenic personality defects or schizophrenic residual states are characterized by a reduction of ambition, initiative, available energy, and emotional responsiveness. A person in this state may be more withdrawn, more aloof, and more selfish than he was prior to the onset of his illness. He may neglect his personal appearance, and he will almost certainly go down on the occupational ladder. A professional person may at first still hold a professional position, but with reduced responsibility and less scope for personal initiative. He may eventually end up doing menial work well below his educational level. A person with a schizophrenic personality defect cannot readily assume any responsibility. He cannot cope with competitive pressure and cannot tolerate time pressure. He is best suited for quiet, routine work he can perform independently from others and at his own pace. Some former schizophrenics, therefore, prefer to do night shift work because it is less demanding and permits them to work alone.

FIGURE 6. "Schizophrenic Withdrawal." (This prize-winning contest photograph is by Sid Bernstein, Research Facility, Orangeburg, New York.)

The degree of personality defect may be so pronounced that the patient is not capable of taking charge of his own affairs but requires continuous protective supervision and sheltered work conditions. If the personality defect is less pronounced, the patient may be capable of living independently and of supporting himself, although at a lower occupational level than before his illness. Often the personality defect is so slight that only the patient's family and close friends recognize the subtle changes that have taken place: a diminished capacity for enthusiasm, a lessened spontaneity, decreased initiative, and a decline in creative imagination. In most daily life situations, the patient may, even socially, function at an apparently normal level.

Full and permanent recovery. The prospect of full and permanent recovery from a schizophrenic attack is considerably brighter than it was a half century ago, when the odds for such complete recovery were only 2 to 4 per cent. The neuroleptic drugs now permit the prevention of relapses that could not have been prevented before the advent of these drugs. Previously, it was possible to terminate attacks, eliminate symptoms, and bring about rapid remission of acute schizophrenic breakdowns by use of insulin coma and

electroconvulsive treatment. But only with maintenance drug therapy is it possible to prevent relapses and thereby greatly reduce the risk of personality deterioration.

This possibility constitutes a major stride in the therapeutic battle against the destructive effects of schizophrenia, a stride that certainly promises to lengthen even further as the full potentials of new treatment methods are developed in hospitals and laboratories.

Suggested Cross References

For further discussion of the symptoms described in this section, see Linn's chapter on psychiatric symptoms (Chapter 13) in Area E, on psychiatric assessment. Childhood schizophrenia is described by Eisenberg in Section 42.1. Basic concepts of perception, cognition, and communication, psychological functions that are disturbed in schizophrenia, are discussed in Sections 3.1, 3.2, and 3.6, respectively, in Area B, on the basic behavioral sciences. Other syndromes related to schizophrenia are discussed by Lehmann in Section 32.1, on unusual psychoses.

EDITORS' NOTE ON TREATMENT OF SCHIZOPHRENIA

The etiology of schizophrenia is not yet clearly understood; consequently, treatment is largely empirical. For didactic purposes, in this textbook, the

treatment of schizophrenia has been discussed from two viewpoints, the organic and the psychological. However, clinical experience has shown that the most effective regimen for the treatment of schizophrenia is an integrated effort, combining organic, psychological, and environmental modalities in a unified therapeutic approach, which is carefully individualized for each patient.

For example, the value of antipsychotic medication has been confirmed by many clinical studies. These drugs have been found to be effective in relieving symptoms of acute psychosis and in enabling the patient to maintain his therapeutic gains; studies have shown that such medication may also prevent further psychiatric deterioration of the chronic patient. On the other hand, the prognosis in acute as well as chronic cases is stated by some to be even more favorable when the therapeutic program includes psychological, as well as pharmacological treatment. Such psychotherapeutic techniques as the establishment of a supportive relationship, strengthening of the patient's psychological defenses, and help with reality testing may facilitate recovery by helping the patient to improve his tenuous adaptation and overcome his emotional isolation. Psychotherapy has been advocated by certain clinicians for protection against subsequent psychotic episodes. During hospitalization, the organization of a specially structured therapeutic environment may expedite recovery and limit the deterioration of the schizophrenic patient. After discharge from the hospital, the use of such resources as the sheltered workshop often facilitates his return to the community. Schizophrenia is as yet not curable; however, the judicious use of these different, but complementary treatment methods offers many patients a good prognosis for social remission.

15.5 SCHIZOPHRENIA. V: PSYCHOLOGICAL TREATMENT

OTTO ALLEN WILL, JR., M.D.

Present psychiatric knowledge does not permit the formulation of a precise, detailed account of the theory, technique, goals, and expectations of a psychotherapeutic approach to the problem of schizophrenia. It is possible to outline certain characteristics of the disorder, the therapeutic relationship, and major difficulties in treatment, but the intricacies of the work reflect peculiarities of therapist and patient (their backgrounds, value systems, and personalities)

and of the culture (hospital and community) in which the program is carried on. The therapist has experience, training, and skills that identify him as a professional. The patient displays behavior (signs and symptoms) that identify him as one in need of help. The therapeutic transaction, however, includes not only the meeting of a professional and a patient but also the developing relationship of two human beings, aspects of which tend to remain private—defeating observation, reporting, and formulation into meaningful communicable roles. Psychotherapy continues to be, to a large extent, both subjective and an art.

The therapeutic approach is a result of the ways in which the therapist conceives of human personality in terms of growth and development, his view of the modes of operation and significance of behavioral patterns labeled pathological, and his use of technical procedures. Every therapist works with ideas—perhaps convictions—regarding these areas of interest. It is not necessary that theories be right in all respects, but it is important that the therapist be aware of his theories, be able to attend to their defects as well as their virtues, and be willing to encourage change and growth when a system of ideas is found to be unsatisfactory, limited, or restrictive. In brief, the therapist will find it useful to formulate concepts relevant to what he is doing professionally; otherwise, his work may be disadvantaged by motivations—private and unsystematized—that operate outside of his awareness.

There are a number of opinions about the nature of schizophrenia and the appropriateness of various therapeutic approaches. In this section on treatment, attention is devoted to the history of the concept of schizophrenia and to the onset and development of the schizophrenic process, thereby suggesting that the therapeutic approach is properly derived from the way in which the disorder is conceptualized.

History of the Schizophrenia Concept Relevant to Therapy

People's ways of living are simply human, whatever the form of their expression may be, and the performances of the mentally disordered are to be comprehended in terms of the commonplace activities of any one of us. The term "schizophrenia" describes complicated or sometimes overly simple patterns of behavior devised to make possible a person's continued existence with his fellows, and these patterns may have been used—unhappily and with varying success—from the earliest days of men's living together. Behavior suggestive of what is today called schizophrenic has been described in times long past and is not a phenomenon of recent or, perhaps, even historical times.

Psychiatric history continues to live in the present in the sense that theories and practices of the past are maintained in the present, long after they might have been expected to become obsolete. Thus, concepts of

schizophrenia as the reflection of evil living or devil possession or as the mysterious expression of a never to be comprehended fate still live with us. Nevertheless, whatever the explanation given at various periods in the development of a concept, the underlying concern is with making sense of phenomena that are troublesome to man or that otherwise attract his attention. Throughout the history of schizophrenia runs the thread of man's persistent need to explain and find significance in the universe and his ways of dealing with it. Alongside this need there is the confidence of at least some people that human behavior has meaning, is goal-directed, and is subject to understanding.

What is now generally called schizophrenia was termed "dementia praecox" by Benedict Morel in 1860 in his description of an adolescent boy's withdrawn, melancholic behavior, considered to be the early transitional steps toward an irrecoverable state of personality disorganization. This pessimistic prognostic view was in keeping with Morel's conception of psychiatric disorders as being expressions of degenerative processes of the central nervous system, possibly set in motion by hereditary weaknesses, toxic influences, and unidentified brain diseases.

Although dementia praecox, catatonia, hebephrenia, and paranoia were not considered to be related to one another functionally, it was suggested that they all arose from unknown constitutional or hereditary defects or from destruction of brain tissue by toxic agents or unspecified degenerative changes. It was thought that they always led to an irreversible state of organic and habit deterioration that was unresponsive to any mode of treatment.

In 1896 Emil Kraepelin suggested that there was a relationship among the catatonic, hebephrenic, and paranoid states and included these as subgroups under the general rubric of dementia praecox. Emphasis was placed on the supposed outcome of disorder—deterioration—and favorable changes in some patients were thought to be instances of faulty diagnosis. Attention was turned to problems of diagnosis and a search for etiology in the realms of anatomy, chemistry, tissue pathology, and physiology. Treatment was not generally related to the personality of the patient, who seemed to be doomed by his diagnosis, being institutionalized and becoming one of the living dead.

In the early years of the 20th century this grim view of dementia praecox began to be altered, although it should be noted that the earlier concepts of progressive organic deterioration secondary to metabolic or other defects continued to be highly regarded. Sigmund Freud spoke of psychotic behavior as reflecting a conflict between the ego and the environment; there is a regression of the personality to an earlier developmental era, as in infancy. Although the standard psychoanalytic procedures were not considered suitable for the treat-

ment of the schizophrenic person because of the difficulties in developing a communicative relationship, such concepts as regression, transference, and the unconscious opened the way to the psychological study of schizophrenia and the development of psychotherapeutic techniques.

In 1911 Eugen Bleuler used the term "schizophrenia" to describe what he called a "splitting of the psychic functions." He suggested that the psychosis arose from organic disturbances that had been shaped by psychogenic events.

Adolf Meyer, in 1910 and later, suggested that dementia praecox was not a disease entity in the usual sense of the term, but was a complexity of behavioral patterns developed by the organism in efforts to deal with its progressive difficulties in adjusting to the demands of its environment. Unable to cope with his life situation, such a person withdraws into rumination and day-dreaming, turning away from further social involvement. Meyer emphasized the organism's struggle in working out a satisfactory adaptation to the culture and the physical world. He was critical of the concepts of constitutional, organic, and toxic etiology.

In the 1920's Harry Stack Sullivan emphasized the influence of the culture in the forming of a human being's characteristic ways of behaving. He described schizophrenia as arising from a background of disturbed interpersonal relations within the family and insisted that behavior could not be understood adequately without reference to the social situations from which it arose and in which it was currently displayed.

History of Treatment of Schizophrenia

Early treatment theories. Once schizophrenic behavior was looked on as something other than a mysterious representation of occult influences, attempts were made to deal with it in terms of the classical medical model. The patient's activity was thought of as reflecting changes in the central nervous system; these changes were, in turn, the results of biological inadequacy or attack by various noxious agents. The patient was described as *having* a disease that could be identified by signs and symptoms related to a causative agent and associated with demonstrable structural changes. The symptoms, such as hallucinations, might be without meaning other than their connection with organic dysfunction, and the physician's task was to identify the disorder and attempt to remove it from the patient by treatment, thus restoring him to a state of health clearly defined and previously enjoyed. Should the difficulty be the result of a progressive degeneration of the brain, etiology unknown, there was little to be done. Under the influence of such theories, psychotherapy of the psychoses was not likely to flourish.

Recent treatment theories. In recent years man has been pictured as less instinct-bound than he was

once thought to be, and attention has been turned to his involvement with the culture which he creates and by which he is, in a social sense, created. Through his unique ability to devise and use symbols, man has the remarkable capacity to be educated in terms of recorded racial experience; he can modify what he is by reference to his past, his present, and, through the use of foresight, his future. Human behavior can be conceived of as reflecting a given biology—usually of much greater potential than is realized in a lifetime—molded by interpersonal and cultural experience into patterns that more or less satisfy biological and social demands. Troublesome deviations from approved standards may be variously labeled as criminal, sick, and wicked. When the deviation is called psychiatric illness, or mental disease, its possible meaning must be sought for not only within the body or the mind but also in the social transactions in which the person has, does, and expects to carry on his living.

From this point of view, psychiatric disorder may be thought of as arising largely from participation in social fields and as having significance in terms of past, present, and future involvements in such fields. Since the troubled behavior has to a great extent been learned and has purpose and thus meaning in a symbolic sense, it is, theoretically at least, subject to change through the discovery of its goals and meanings and through the application of techniques that will promote modification of inefficient and harmful modes of operation and open the way to new learning. With the formulation of such concepts, the psychotherapeutic approach to schizophrenia is seen to make sense. The patient is no longer seen exclusively from the perspective of being biologically defective or the carrier of a disease reflected in odd and meaningless behavior. Rather, he is seen as a human being who acts as he does in order to be able to continue living with his fellows and at the same time maintain a semblance of self-respect and a feeling of security—motivations that often appear to him to be mutually incompatible.

Development of a psychotherapeutic approach.

Prior to the 1920's there was little written about the psychotherapy of schizophrenia and little interest in this sort of enterprise. In the 1920's Sullivan reported his work with male schizophrenic patients at the Sheppard and Enoch Pratt Hospital in Towson, Maryland, and in the 1930's, Fromm-Reichmann presented her observations of therapy at Chestnut Lodge in Rockville, Maryland. During the past 20 years there has been a marked increase in this form of therapy. The range has been broadened to include studies of the families of schizophrenic people, cross-cultural studies, and family and group therapy. At present there is a growing concern with the therapeutic influence of the milieu in which the patient lives and with the extension of community facilities

for treatment outside of hospitals—a development referred to as social psychiatry.

Therapists. When one thinks of those who have had much experience in the psychotherapy of schizophrenia, he turns to those who have reported what they have done, although some of the most gifted and effective therapists do not write or speak publicly about what they do. The personalities and reported techniques of various prominent therapists vary one from the other, but there are certain common qualities in what they do.

Harry Stack Sullivan was a quiet man who was remarkably alert to what was going on in the therapeutic field. Insistent on precision in observation and reporting, he had little patience with theorizing not closely tied to repeatable observation. Although he had great respect for the influence of past events on the current scene, in treatment he focused on the here and now, the area in which patient and therapist were both participant and observer. Placing great reliance on man's tendency to make use of simple and effective modes of behavior once he has an adequate understanding of his own and others' motivations, Sullivan sought to further such knowledge by bringing obscurely perceived motives and impulses into awareness.

Frieda Fromm-Reichmann, a small but determined woman, had an unusual empathic responsiveness to the needs of the gravely disordered and a deep appreciation of and respect for the assets of her patients. She epitomized the healer without losing a useful, cool objectivity.

Paul Federn suggested that the schizophrenic patient be dealt with in such a fashion that repression was encouraged and regressive tendencies prevented. Every effort was made to develop the patient's trust in the therapist, who was advised to be supportive and completely sincere. The male therapist was aided in his work by a woman helper, and this use of a co-worker or assistant was also advocated by Rosen.

Marguerite Albert Séchehaye pictured the schizophrenic person as suffering from frustrated satisfaction of essential needs early in life. She devised a therapy to fulfill these needs in part, though she used a form of symbolic realization in which current responses to the patient symbolized responses that would more appropriately have been given to the patient in his early childhood or infancy. Her approach involves not only understanding, but the creation of a maternal and protective environment with a deliberate modification of reality demands.

John Rosen uses a direct and forceful approach to the patient, quickly asserting himself as both a realistic and magical powerful figure with whom the patient cannot avoid relating. He fearlessly and directly confronts the patient with interpretations of the patient's unconscious motivations, reinforcing his position with trained assistants who work in close conjunction with him.

Harold Searles, as a result of many years of intensive therapy with chronically ill schizophrenic patients, emphasizes patience and the paying of attention to the therapist's own feelings and impulses as clues to those of the patient. He relies on interpretation of the patient's behavior and a confrontation of the patient with the intensity of his involvement with the therapist.

Therapeutic approach. Of particular concern here are the common qualities in the therapeutic approaches of various therapists—those mentioned above and others. Although it is difficult to learn how a therapist works from even the frankest written reports, the therapists of schizophrenic patients do seem to have the following attitudes in common.

1. The patient is not viewed as hopelessly diseased or as some inferior caricature of a human being. His behavior, however seemingly incomprehensible, is thought of as having purpose and as being subject to understanding, although there is no insistence that everything be understood.

2. Behavior is seen as related to past experience, but emphasis is placed on the comprehension of therapist-patient interaction in the mutually observable present.

3. Attention is paid to the symbolic significance of nonverbal as well as verbal activity.

4. Reliance is placed on a developing human relationship as a major factor in reducing anxiety, advancing insight, and providing opportunities for learning and for further expression of the personality.

5. The therapist has respect for his patient and develops a fondness for him that is not restrictive but permits growth and includes a recognition of eventual separation with the conclusion of treatment.

6. The therapist has hope and the expectation of improvement and will not be defeated or driven away by the patient's behavior.

7. The therapist insists on attempting to define his relationship with his patient, refusing the patient's attempts to avoid such definition by his withdrawal or his insistence that he can never change, that there is nothing the matter, and that the therapist is of no significance to him.

8. The therapeutic involvement is viewed as a transactional and interactional process in which both patient and therapist are required to observe and participate, in which both will learn, and in which both will be subject to anxiety and will experience personality change and growth. This does not imply that the therapist is no different from the patient. By experience, training, and certain healthier qualities of personality, the therapist is the expert; he must lead the way and, to a considerable extent, be in control of what occurs in treatment.

Operational Definition of Schizophrenia Relevant to Treatment

Although it may be desirable to do so, it is not possible to give a precise definition of schizophrenia

that would be satisfactory to all those interested in the disorder. The purpose of attempting a definition at this juncture is to remind the reader that one's concept of behavior influences his ways of dealing with and treating it. The author's conception of schizophrenia follows.

As used here, schizophrenia is the name of a process of behavioral patterns extending from early infancy and developed largely through interaction with other human beings whose care and companionship are needed but whose motivations are often unclear and conflicting to the schizophrenic. The instability of such patterns may be revealed at times of interpersonal stress when anxiety is increased to the point of panic with an accompanying disruption of previously dependable ways of behaving and personality disorganization. Such states of panic may be resolved through the formation of overly simplified, chronic caricatures of human living, such as the hebephrenic and paranoid developments; through the redissociation of disturbing systems of ideas so that a fragile adjustment is gained, marked by lack of insight and by a cautious avoidance of situations that might favor a recurrence of disaster; or through a reorganization of personality in which resocialization and learning can occur with resultant personality growth and increasing security from further collapse. The concern here is with the patient's past and current behavior in a variety of social fields. It is in the past that personality was structured and in the present that the interpersonal operations called schizophrenic can be observed and modified.

The difficulties that may eventuate in schizophrenia are thought to originate in the infant's interpersonal contacts before he attains a clear definition of himself and those around him and before he acquires skill in the use of speech. Should these early experiences be particularly devastating, development may be so arrested that the infant lies in a marasmic state or survives to become autistic or a childhood schizophrenic. In each instance the individual's in-born drive to exist is markedly reduced by his early contacts with those who care for him. He can reach chronological adolescence without major disaster, although in retrospect his earlier adjustment may appear to have been precarious and marginal. His failure occurs in solving the adolescent tasks of identification, including the finding of satisfying interpersonal intimacy and the dependable patterning of sexual behavior. Faced by such requirements, he reveals defects in acculturation, learning, and the use of necessary interpersonal skills. There develops an increasing personal and social estrangement, marked by disturbances in communication, autistic thinking, and complicated forms of behavior devised to keep anxiety at a minimum and to avoid the intrusion into awareness of disturbing ideas that somehow seem unsuitable to the person's public image and concept of himself. With a failure of dissociation, such ideas enter awareness in dreams and hallucinations. The

attendant anxiety and sense of loss of personal identity may be dealt with through such restitutive devices as delusion and denial.

In attempting to deal with problems such as these, the therapist is interested in the degree of interpersonal security the patient has developed in his growing up and in the ways he manipulates symbolic expression in his seeking to reduce anxiety, to establish a required minimum of communication, and to maintain sufficient human contact to enable him to live.

Onset and Course of Schizophrenia

The structure and goals of psychotherapeutic endeavors can be understood best by considering what the patient may be attempting to deal with—to accomplish—through his disordered behavior. The purposiveness of actions that often seem to occur without design or goal may be illuminated by reviewing events characterizing the onset of the difficulty, the emergence of the well defined psychotic process, and the movements toward its resolution.

As used here, the term “schizophrenia” refers to behavior appearing late in a series of increasingly complicated and unsatisfying adjustive efforts made in response to situations that the person experiences as intolerable and beyond his capabilities to meet. They may not seem threatening to someone less handicapped by earlier life events. Often such efforts go unnoticed, or their significance is not recognized. In the early stages the behavior may not be widely divergent from the norm; it may seem natural in the setting in which it occurs, and observers may seek to avoid their own anxiety by failing to extend the implications of their observations.

Time of onset. It is often difficult to identify the time of onset of disorder—the period in which increasingly maladaptive behavioral patterns are to be labeled schizophrenic. The beginnings of the psychotic disturbance are perhaps to be found in the interpersonal experiences of the infant, when he is forming early concepts of identity and is developing skill in the use of language and the manipulation of other symbols. It is assumed as a working hypothesis—to be tested by direct observation of growth and development in human and other organisms—that the infant deals with the exposure to recurrent severe anxiety by the avoidance of behavior and the dissociation of concepts that threaten to disturb the continuation of the needed supporting relationship with those who care for him, particularly the mothering person. Although such an infant may survive, he fails to develop the confidence and trust in himself and others that will enable him to make adequate use of later opportunities for learning. This infant may become a “good” child in that he is compliant and appears to adjust well to the conventions of his group, but the process of dissociation and the failure in trust go unnoted and uncorrected.

The eventual revelation of trouble and the need for psychiatric care may come as a surprise to those who supposedly have known the patient well. This suggests (1) that the illness was an acute process without known antecedents; (2) that its earlier manifestations were too obscure to be observed; (3) that the developments could have been noted but that the implications of the behavior were felt to be distressing and threatening, and thus much of importance was ignored, or (4) that the ailing person's social role differed markedly from his personal concept of himself and that in certain vital respects he was a stranger to his fellows despite his seeming conventional success. The third and fourth points are relevant to the thesis presented here.

The diagnosis of schizophrenia is often made only after the exhibition of behavior that is disturbing or unacceptable to others and that could readily be labeled by the nonexpert as crazy. Much of the patient's earlier behavior may have been close enough to conventional norms to go unnoted or to be looked on as transient peculiarities of little significance. From this point of view, there are no clear cut, fundamental distinctions between what we call normal, neurotic, and psychotic phenomena; these may best be understood as existing on a continuum in which one merges, often imperceptibly, into another.

Early life experiences. Faced by the acutely disturbed schizophrenic person, the psychiatrist might make the following crude and oversimplified conjectures about his earlier experiences.

Despite reports of apparent stability, the family in which schizophrenic behavior develops is marked by anxiety and by gross contradictions and obscurities in communication. In such a setting, the identities and relationships of the various family members are poorly defined, and complicated forms of behavior are elaborated to make seeming sense of incompatible motivations and demands. What eventually appears to be crazy behavior may have been devised as the only way to maintain a semblance of relatedness and normality in a crazy family.

The personality defects incurred in earlier life experiences were not corrected adequately through experiences in later years but were not so severe as to interfere grossly with socially acceptable performances in childhood and adolescence.

In early adolescence a person is required to move rapidly in establishing his public identity and his self-concept, there ideally being an approximation of one with the other. At that time he must define his sexual interests, be able to engage in an intimate and communicable relationship, begin an emotional if not geographic separation from his family, identify himself with a vocation, develop predictable patterns of behavior with a variety of people, and elaborate a meaningful system of values. In all these activities the adolescent must relate to other people. It is in this interpersonal area that the preschizophrenic individual

is handicapped by the anxiety that close contact with another person rouses in him and by his persisting low self-esteem, exaggeration of his destructiveness, and devaluation of his abilities.

In an effort to cope with a feeling of social and interpersonal inadequacy, the young person may withdraw from others, unwittingly substituting simpler but socially acceptable behavior—such as day-dreaming, absorption in reading and the watching of movies and television, and preoccupation with hobbies carried on without the help of others—for activities requiring more direct interpersonal associations. Thus he may desire friendship but not take the action and accept the risks in finding a friend. With increasing cultural demands, the threat of anxiety grows, and the oversimplification of experience is no longer adequate, as it carries with it the painful cost of growing isolation. For a time the problems may be dealt with through the use of complex patterns of behavior, both overt and covert, substituted for more simply goal-directed processes and still in keeping with approved cultural requirements. Socially approved “good” behavior may substitute for more direct expression of sexual and other needs. Obsessional thinking and action may reinforce the defenses against the exposure to anxiety. For most people, such defensive activity does not resolve basic difficulties. The presence of anxiety is revealed in disturbing dreams and the person’s discomforting feeling that, unless he moves with great caution, some strange and evil aspect of himself will be revealed to his great disadvantage. Careful observation of someone on his way to becoming openly schizophrenic will lead one to feel great respect for the courage and psychological dexterity displayed in attempts to maintain some sense of security in human relationships in the presence of ever threatening anxiety and chronic uncertainty regarding a sense of personal identity.

Development of overt schizophrenia. As withdrawal and the accompanying feeling of isolation increase, autistic and distorted perceptions of other people are not corrected through discussion with friends. In attempting to maintain needed human relationships despite mounting anxiety, the patient to be replaces the more direct and conventionally acceptable adjustive processes used earlier with complex behavioral patterns no longer in keeping with accepted systems of social ideals. Such behavior—convenient forgetting, rationalization, the transfer of blame to others, and selective inattention to potentially troublesome events—is, despite its usefulness in attenuating anxiety, dangerous in that it invites social disapproval and may lead to further estrangement. By this time there often appears a variety of somatic complaints, such as fatigue, headache, changes in body weight, and restlessness. Sleep is disturbed by dreams, the remembered fragments of which suggest impending disaster; and the

mood may resemble a combination of anxiety and depression.

The person caught up in this situation knows that he is troubled but is unable to define his difficulties and cannot ask for help. His position is complicated further by his long avoidance of intimacy, by his concern that self-revelation may be disastrous, and by his expectation that one is more likely to be hurt than benefited in a human relationship. The inability to formulate a statement of the problem and to communicate this to others is reinforced by friends who overlook evidences of distress and meet poorly expressed requests for help with reassurances that “everything is all right” and that the complaints are “nothing more than a part of growing up.”

This pattern of behavior suggests that important aspects of past experience required for the integration of satisfying human relationships are not available to the patient’s awareness; that is, they are dissociated or repressed. Such systems of ideas may symbolize episodes marked by intense anxiety and not clearly comprehended or formulated into communicable gestures, such as speech. Ordinarily, the content of awareness is restricted to refined referential processes that can be organized and communicated, symbols of disturbing events being kept from awareness by a variety of behavior patterns described as defensive and designed to maintain a sense of security from the threat of anxiety. In the schizophrenic person, the time comes when awareness can no longer be confined to those more precise thought processes that can be validated with others, and frightening representations of earlier troublesome experiences become part of the content of consciousness. These intrusive ideas appear as puzzling, threatening generalities, the meaning of which is unclear; they are difficult to bring into personal focus despite the implication of their personal significance. Such phenomena are heralded by increasing anxiety, a vague apprehension of impending disaster, and disturbing dreams. The appearance of auditory hallucinations is a clear cut expression of a dissociated system of ideas, reflecting both past and present interpersonal involvements. The complex of ensuing psychotic behavior may be viewed as an attempt to solve a problem and also as a metaphorical statement of the patient’s role in his struggle with family members and others.

As the patient’s ability to communicate fails, he is imperiled by the growing sense of isolation, experienced in its extreme as a loss of the sense of self, as a disintegration of the personality, as the destruction of all human relatedness, and as a disappearance into a chaotic, horrifying universe devoid of form and meaning. Panic, a state of disorganization with a loss of personal and object identities, is intolerable and requires rapid resolution. In efforts to bring definition, meaning, and termination to a state of chaos, the patient may take violent action,

such as assault and self-injury, and make elaborate pseudo explanations of events, whereby he publicly reveals himself as psychotic.

Forms of behavior. As noted earlier, the state of panic may be resolved through the development of forms of behavior of variable social acceptability and utility. In brief, some possibilities are these: (1) Further dissociation is established, former defensive operations being put to use and reenforced. (2) Experience is reformulated to fit oversimplified and stereotyped explanations of living, which are often uncomfortably similar to the hostile, prejudiced, suspicious views of many who are not formally looked on as ill. This is the paranoid solution. (3) There is a retreat into an apparent preoccupation with fragmented ideas and bodily processes, accompanied by a deterioration of conventional modes of behavior, including patterns of speech. This is the hebephrenic solution. (4) Unstable adjustments may be developed, the patient being recurrently beset by panic and hallucinatory episodes, apparently unable to structure a more durable method of harmonizing personal and social demands. (5) In some instances a human relationship may be established in which confidence in self and others is increased, anxiety allayed, autistic ideation and perceptual distortions modified, opportunities for new learning provided, and a restructuring of the personality made possible. It is with this last possibility that the psychotherapist is concerned.

Concept of Psychotherapy of Schizophrenia

Both the psychiatric disorder and the therapeutic intervention may be thought of as special instances of social processes, reflecting past and dealing with present interpersonal relationships. In the disorder, old patterns of action may be repeated again and again with little useful modification; they are retained not only because of their usefulness in reducing anxiety but because the person concerned has become accustomed to them. They have been learned so well that they seem to be a natural part of the individual, and alternatives to them are not considered or seem to be unimaginable. In the therapeutic situation, such old patterns are also repeated, but in a setting that, in order to be useful, differs significantly from the patient's past. The therapist displays his expertness by helping the patient recognize the form, goals, and origins of his destructive actions and by dealing with these in a more benign fashion than have many people in the patient's earlier life. Limits are set so that there need be no fear of the possible consequences of expression of impulses, and a controlled setting is provided, wherein there is an opportunity to observe and modify the illness.

From this point of view, the illness is looked on as a complex way of behaving developed throughout the years in response to anxiety-provoking, often obscure and threatening interpersonal relationships. The therapeutic encounter is also an interpersonal relation-

ship, but it is structured not only to permit the exposure of reflections of past experience, learning defects, and developmental deficiencies but also to offer a new form of relationship that will favor the reduction of anxiety and the promotion of learning.

The therapeutic task. The intricacies of psychotherapy cannot be precisely defined or demonstrated, and so it is not possible to design a therapeutic system of techniques to be applied impersonally to someone labeled a schizophrenic patient by someone else designated a therapist. The psychotherapeutic intervention is an involvement of two people (with the aid and hindrance of both real and illusory others)—a therapist with certain experience and expertness, and a patient who is anxious, frightened, hostile, shy, subject to shifting perceptual impressions, and burdened with a sense of identity that is at best unclear and at worst derogatory. About the proposed treatment situation, some general recommendations can be made with assurance. The application and the modification of these recommendations will be functions of the peculiarities of the patient, the events in which he is involved, and the personality and skills of the therapist. In other words, there are as yet no fixed rules for charting such a human encounter.

Here consideration is given to therapy with the more acutely disturbed schizophrenic patient. The therapeutic task with the chronically disordered patient, such as one who has settled into a hebephrenic or paranoid way of existence, is complicated by the patient having found a solution that, unsatisfactory though it is, he is loath to give up when he has no assurance that he will find something better. A further complication is the problem of chronicity, the patient having become so imbedded in the institutional environment that the problem is no longer schizophrenia alone but is also one of bringing hope and motivation to a human being sunk in a quagmire of hopelessness and despair.

Characteristics of the schizophrenic patient.

It may be useful to review briefly some of the characteristics of the person who becomes a patient and attempt to predict how he may behave in treatment. On the basis of views regarding the development of the disorder and the significance of the behavior, it should be possible to work out a rational therapeutic approach consistent with these views. To do so is an improvement over the setting up of rules or prescriptions to be followed blindly.

Despite the vicissitudes of his living, the acutely disturbed schizophrenic person is bound to people by strong and enduring ties, suggesting that there were positive as well as negative aspects to his early life experience. Although relationships were marked by anxiety and he often acted as if he expected to be hurt, he has persisted in having something to do with people. Having learned not only that he needed people but also that he was made anxious by them,

he was faced by a common dilemma—how to avoid the extremes of both anxiety and loneliness.

The patient's efforts to establish meaningful, lasting relationships were complicated by the dissociation of certain motivations and systems of ideas that would be brought into awareness, with attendant anxiety and perceptual distortion, as intimacy grew. Additional handicaps were provided by the persistence of autistic concepts difficult to communicate, defects in the acquisition of social skills—such as how to cope with envy and jealousy—and the anticipation that entering a relationship eventually leads to one's being revealed as inadequate and repulsive.

In the therapeutic situation the patient is brought into contact with that which he both needs and fears—a human relationship. The usual ways of dealing with anxiety are to flee its apparent source, to destroy its source, or to erect and strengthen psychological defenses against its experience. In treatment the first two are blocked, and the necessity for the latter is explored, with the intent of usefully modifying the psychological defenses. As limits are set to the patient's activities through hospital restrictions or, when less disturbed, rules to which he must conform, his anxiety will increase and his ambivalent attitude toward people will be revealed. Periods of the patient's seeming growth of confidence in the therapist will be replaced by times when the patient doubts the therapist's motives and usefulness. The relationship is characterized by approach and withdrawal, trust and suspicion, hope and disappointment. As the patient moves toward greater intimacy, he may express his growing discomfort by complaining about being controlled and dominated, by discovering that the therapist is (as the patient generally expects people to be) dishonest, destructive, evil, and in various ways like significant people in the patient's past. As dependency increases, so also will the need to take flight or to attack. These tendencies being restrained, dissociated impulses may reappear, apparent improvement being swept aside for a time by psychotic behavior. The perceptual distortions of others and of self will frequently be so great that the therapist will find it difficult—if not, for the time being, impossible—to identify, define, and trace distortions to their origins or comprehend their functions in the current scene. Each participant will often be uncertain about the roles in which he and the other are at the moment involved.

As the patient becomes caught up in a closer relationship with the therapist, other complexities may arise. The patient may then fear that he will kill or somehow magically destroy his therapist, drive him insane, or cause him to take flight. He may feel that he himself must take care of the therapist, who is experienced as being weak and frightened by the patient's increasing self-sufficiency. The patient may repeat with the therapist aspects of his relationship with members of his family, who may have become

so involved with him and his sickness that he believes they will be hurt or demolished if he asserts his independence and turns his attention to interests other than theirs. The patient may feel that forming new relationships and becoming healthy will make him a murderer of his therapist and relatives, whom he envisages as requiring his continuance in his sick role in order to insure their physical and psychological survival.

In other words, the patient may become concerned that his own emotional development will be a source of discomfort to his therapist and that dependency—so difficult to achieve and accept—will be encouraged by the therapist, who is pictured as needing people to be dependent on him. The patient must then learn that the dependency of childhood is a useful and necessary preliminary phase in gaining the independence and relatedness of adult life and that a major task of both parent and therapist is to take pleasure in forwarding a child's and a patient's growth and ability to separate as each creates, as best he can, his own existence in accord with his abilities and opportunities.

Social components of the schizophrenic's behavioral disturbance. As presented here, schizophrenia is not a disease entity in the conventional sense; it is a complex of recurrent behavioral patterns originating and manifested in a variety of social fields. The disorder does not exist *within* a person and treatment is not *given* to him. What is observed and modified are interpersonal transactions, such as (1) the patient-therapist relationship, (2) transactions in the ward-hospital milieu, (3) the family relationships of the patient, and (4) interactions with the larger culture within which these exist.

If the patient lives outside the hospital, the therapist may have little or no contact with the patient's associates, and so he must rely on what takes place in the therapeutic sessions for the data required to carry on the work. If he decides that contact with someone else (for example, the family) would be advantageous, he should arrange for the desired interview after discussing his plans with the patient; at times he should include the patient in these other meetings.

If the patient is hospitalized, his exercise of responsibility for himself is greatly curtailed, and he becomes a part of the institutional social system, subject to control by hospital personnel and the influence of significant family members. The therapist cannot ignore the various forces affecting his patient's living; what is done in the individual therapeutic sessions may be advanced or hindered by what occurs elsewhere. The patient's behavior will influence and be influenced by the activities of other people; that is, shifts in one part of a social field will require accommodations in other parts, although the relationship of these changes to each other may be obscure and go unnoted. For example, supposedly desirable

improvement, reflected in increasing independence and self-assertiveness, may provoke a relative to arrange the patient's transfer to another hospital on the grounds that matters are getting worse. The change in a patient requires a reciprocal alteration in the relative or, to put it more accurately, in the social field of the family. For example, a mother accustomed to looking on her son as a weak, ineffectual, hopeless hospital patient will have to alter her behavior in order to respond appropriately to him when he no longer finds the psychotic role necessary or desirable. If it is easier for her to accept her child's chronic illness than to make the required adjustment to his improvement, she may remove him from the therapeutic situation, which seems to threaten her by producing healthy changes in the patient.

Psychotherapy is not carried on in a vacuum, and no amount of discussion will correct all of the disasters in the patient's life. Unnecessary difficulties arising in the social fields of the hospital and the family should be recognized and prevented. It is advisable for the therapist to have direct contact with the patient's family and those who care for the patient on the ward. To avoid complicating involvements, the therapist can be helped by the nurse, the social worker, and the ward administrative physician.

The use of adjuncts to individual therapy in the form of family, group, and milieu therapy will not be discussed here. It should be evident however, that in an institution these various modes of treatment must be coordinated. And since social organizations are marked by the presence of envy, jealousy, competition, cruelty, and misunderstanding, efforts to bring about the coordination of various workers to produce a therapeutic environment present interesting and vital problems in communication and cooperation.

Initial interview of the patient. The first meeting with a patient is designed to create a situation in which mutual observation can occur without the arousal of great anxiety and in which there can be a demonstration in miniature of some of the major features of the course of psychotherapy. To avoid becoming unnecessarily prejudiced, the therapist will often choose to learn what he can directly from the patient, consulting case records at a later date.

If the patient is mute and withdrawn, the therapist may be content to sit quietly nearby, occasionally speaking about the hospital setting and his function in it and speculating about the purpose of some of the patient's more obvious behavior. As the therapist does not know a great deal about the patient and his troubles and has no ready solutions to offer, a quiet and modest attitude would seem to be suitable to the occasion. The therapist should show that he is willing to give time to observing what goes on and learning something from it.

Should the patient be assaultive, precautions must be taken so that neither participant will be injured.

When fear is a major factor in an interview, there will be little learned, and there should be no hesitancy in telling the patient directly that physical violence cannot be tolerated and must be controlled. Sometimes the presence of one or more assistants in the room will make both patient and therapist feel more secure. It is well to remember that the patient may feel threatened by the therapist and, from his point of view, also require protection. Occasionally the patient may be restrained in a sheet pack, the therapist sitting close by and well within the patient's range of vision so that he can watch the therapist's movements and not be frightened by the thought that things are going on without his knowledge.

If the patient is hospitalized but can come more or less willingly to the office and talk with the therapist, it is well to set aside 2 to 3 hours for the first meeting, the exact time to be adjusted to the needs of the participants. After introducing himself, the therapist asks the patient to describe what he considers to be his ailment, interrupting the ensuing account only to clarify any obscure aspect of it. After the patient has had the opportunity to express himself fully—a period varying from a few minutes to perhaps an hour—he is asked to talk about his growing up. Thus the therapist obtains a general history of the patient through a seemingly casual discussion rather than by following a chronological outline. As before, questions or comments should be used only to prevent possible misunderstanding.

After completing the outline of the history, the patient is again asked how he views his ailment. This second description of what disturbs him may vary from the earlier one, since he now knows the therapist better, may be more at ease, and can consider his troubles in light of the review he has just made of his past. The therapist may then ask how the patient views him (the therapist) and what he thinks can and should be done to alleviate the difficulties described. In return, the therapist succinctly sums up his conception of the patient's predicament, using language that makes sense to both parties.

Throughout the interview the therapist observes movements of anxiety in himself as well as the patient, attempts to identify the events associated with the anxiety, and acts to keep it within tolerable limits. "Searching" interpretations, more often designed to display a therapist's brilliance than to illuminate a patient's problems, are to be avoided, but an effort is made to establish tentative connections between certain current behavior and past experience. Gross perceptual distortions are pointed out, their correction being more likely to occur when the event can be observed in the present by both participants.

In concluding the interview, the therapist briefly explains the plan for further meetings and invites comments and questions, to which he responds as clearly and simply as he is able. If the therapist does

not know the answer to a question, he should say so; it is not useful for the therapist to attempt to give the impression that he knows everything or that he is being evasive or hypocritical. Following the session, the therapist should write as detailed a report as he can, commenting on his own reactions of anxiety, annoyance, liking, and so on, and making a prediction about the course of treatment without feeling bound to honor it in the sense that he must make it come true. No notes are taken during the interview; to do so would interfere with both observation of and participation in the therapeutic field.

Course of therapy. The beginning psychotherapist need not immediately equip himself with the impedimenta of technical rules and scientific descriptions of disorder. He will probably have some acquaintance with these, but it will be useful for him to sit on the ward of a psychiatric hospital for long periods during the day and the night, trying to make sense of what he observes, without reference to what others say he ought to see. First, he learns to look at the scene, discovering how difficult this task is when one is anxious. Having looked, he notes what seems to make sense and what doesn't, including in this judgment the behavior of staff members as well as of patients.

Next, he might sit in a room with a schizophrenic patient without being required to do anything; he doesn't have to know it all, need not set about curing a mental patient, and should not be required to protect his self-esteem by putting on demonstrations of being a better therapist than someone else. Relieved of some of the burdens associated with the attaining of certain personal and professional goals, the therapist has the opportunity to observe events in ways that will never be available to him again; knowledge and sophistication may increase his ability, but they will also alter the freshness of his outlook. Occasionally he may discover that his respectful presence and his willingness to learn without the need to enforce the acceptance of his own views may be accompanied by favorable changes in the patient's behavior. Should this occur, ambition and professional zeal must not be allowed to replace modesty; if they do the patient may again retreat.

In this short account there can be no detailed description of treatment. There follow a few problems that commonly occur in psychotherapy with schizophrenia. The ramifications of therapy can be dealt with more effectively in seminars and in discussions with other therapists, reinforced at times by the study of recorded interviews, transcriptions, and motion pictures and by the use of one-way screens.

The therapist as the object. In the early stages of treatment and to some extent throughout its course, the patient acts as if he were caught up in a cage with a strange, puzzling, and fearsome object—the therapist. The patient is restricted by the hospital, the office, or the rules of the game; he cannot escape,

and he is prevented from destroying that which he fears. No matter what he does, he is placed in contact with another human being in an effort to develop a communicative relationship.

Much of what happens in these early stages can be talked about in terms of the patient's need to explore this object, finding out how it works and what its potentials are for good and evil. The course of the relationship will often be uncertain, seemingly unpredictable, and marked by sudden changes. The following are examples of the vicissitudes of this aspect of treatment and possible therapist responses—not always suitable or necessarily correct.

1. The patient may not wish to meet with the therapist in his office—or anywhere. Fundamental to psychotherapy is the meeting of the participants at frequent intervals for long enough periods of time to permit emotional arousal and to make an impact on each other. At the beginning of treatment it is useful to hold five to seven hourly sessions each week, the frequency and length of meetings being altered in accordance with the patient's needs. Should the patient be too anxious to remain in the office, the therapist may go to his room on the ward. Should any room be experienced as too confining, therapist and patient may sit in the hallway, walk across the fields, or ride in a car. As mentioned earlier, companions or a pack may be used when assault is a threat. Although ataractic drugs may be of use in some instances, in the author's opinion it is wise to attempt to form a psychotherapeutic relationship without a chemical modification of perception.

The purpose of the regular, frequent meetings is to provide a situation in which relational bonds can be established between the participants. When two people meet recurrently over a period of time with the accompaniment of emotional arousal, ties are formed between them. It is the task of the therapist to prevent the development of an attachment that is crippling or destructive, remembering that people can be bound to each other by hatred and anxiety as well as by affection.

2. The patient may question the therapist about himself, his antecedents, and his current purposes, thus displaying an interest in him. At other times he may appear to be indifferent to him, turning his back, reading a book, looking out the window during long silences, or walking ahead of him on rambles as if he were not present. At other times he may turn on the therapist with a vindictive verbal, if not physical, attack, often being painfully accurate in his observations of personal idiosyncracies and clumsiness. Periods in which tenderness and a semblance of regard for the needs of the therapist are shown are frequently interrupted by withdrawal and a reemergence of doubt, fear, and suspicion.

The patient's questions about the therapist may be answered briefly and without evasion, but involvement in detailed self-revelation should be avoided.

The patient has too many worries of his own to tolerate being burdened with the therapist's history or personal analysis.

During silences and periods marked by the patient's apparent indifference, the therapist need say little, occasionally questioning or speculating about what he thinks may be going on but avoiding elaborate interpretations based on inadequate data and more likely to be wrong than right. The therapist should avoid being thought of as reading minds. Sometimes, in a silence, the therapist may look at a book without becoming lost in it; that is, he keeps his attention available but not unremittingly focused on the patient, who may be discomforted by excessive close observation. Although one does generally encourage speech, sound is not always better than silence; there may be profit in silence if the therapist observes when it occurs, what happens during its presence, and its possible significance.

When being criticized, the therapist should listen carefully, as this is an opportunity to learn how the patient views him and others. Credit should be given for accurate observations, and the therapist should not deny some mistake that he may have made, although he should not continue to cry *mea culpa*, as neither he nor the patient will profit from an immersion in guilt. When the patient is in error, this should be pointed out with some questioning as to the basis for his entertaining such views. Possibly the patient will discover that his attack on the therapist is excessive and motivated more by previous experiences with other people than by happenings in the sessions, in which case he can learn how perceptual distortions are brought about by anxiety and the influence of past events. Should the patient deny that he is in error, the therapist need not argue but may simply say "so be it," agreeing that the patient does hold a certain view for the present, without accepting this view as necessarily final. One should be encouraged by this evidence of the patient's ability to express himself.

The therapist may be pleased when things go well—when there is a temporary lull in the storm—but he should avoid responding with cheers and delight. In so doing, he might, by rushing in, crush the transient appearance of a trace of self-esteem. At such times, searching explorations of motivations are not useful, although it may be advantageous to discuss the happenings of more disturbed periods, unless anxiety is thereby markedly increased. The reappearance of psychotic behavior is evidence that the patient has become more anxious, and this is no time for the therapist to be critical or disappointed. Rather, he should attempt to find out what the upset is about. He may discover that, when the patient begins to feel more at ease, he may at the same time become apprehensive that he will be attacked then, when his guard is down. Then the patient must learn that the therapist will not attack, that is, will not willfully

provoke anxiety, and that, although the therapist may at times get angry, he will not retaliate because of the patient's criticism.

3. At times the patient may act as if he expected the therapist to be extraordinarily powerful and evil, insisting that any kindly and tolerant behavior is only a facade that poorly conceals a poisonous destructiveness. On occasion he may withdraw in disgust and loathing, briefly exhibiting psychotic behavior, all of which will suggest that the developing relationship is bringing to awareness and integrating dissociated representations of earlier painful experience.

At such a juncture the therapist should attempt to identify himself clearly by talking or shouting, by interrupting the progression of events if he can, by pointing out who he is, and by spending additional time with the patient. The therapist cannot sit silently by while the patient moves toward a state of panic. Panic is a painful experience no one wants to repeat. No useful learning occurs in it, and there is no guarantee that one will recover from a profound regression. No patient will feel kindly toward a therapist who carelessly or deliberately permits such a condition to develop. Interpretations on these occasions are seldom useful because the patient is too anxious to make sense of them and the therapist can only guess what referents are being symbolically expressed in the patient's behavior. Thus the focus should be on the you-me relationship in the here and now.

The fear of destruction. As the attachment between patient and therapist grows, the patient will at times recognize his affection and need for the therapist but may then become anxious and withdraw. The relationship is characterized by advance and retreat. The patient may say that the therapist is attempting to control him, to foist an unwanted system of values on him, and to make him a slave. In more disturbed periods, he may say that the increasing closeness will bring with it destruction of one or both participants. This reveals the patient's fear of his own aggressiveness—a fear that he may kill the therapist or drive him mad—in which case he may seek to preserve himself and his companion by getting out of the relationship. Then he is faced by the fear of abandonment and isolation.

This behavior is evidence of increasing intimacy in the therapeutic relationship, which is feared by the patient as a return to an anxious, symbiotic attachment (as with a mother) in which the sense of self will be lost and from which there is no escape save through destruction. The patient needs assurance that the relationship will continue despite the intensity of emotion aroused in it. Limits must be set to destructive behavior, and it should be demonstrated that neither patient nor therapist will be hurt or driven away. When the patient indicates a feeling of increased personality disorganization (a loss of the

sense of self, in which the boundaries between himself and other objects seem unclear), the therapist may take pains to help the patient distinguish what is properly his and what is someone else's, in terms of body, mind, thoughts and values.

The therapist tries to find out why the patient acts as if he both fears and needs control and domination; frequently it is discovered that a parent wanted to live aspects of his life out through the child, with the result that the child assumed that he could not preserve the needed relationship with the parent unless he gave in to him, took on his values, and became something of a puppet. The therapist makes it clear that he has his own life to lead and that the patient is not required to take responsibility for it. The patient must learn that, although the therapist can take pleasure in the patient's abilities and in his growth, he does not have the need to envy him or to keep him dependent. The patient also learns that he does not have to take care of the doctor—that is, that the doctor will not become unduly dependent on him—and that, although eventual separation is necessary, it is not necessarily destructive. These matters briefly outlined here are worked over again and again, in both action and verbal discussion, throughout the duration of treatment.

Transference or perceptual distortion in treatment. The early, often vague and confused, view of the therapist held by the patient develops into a concept of him that in some respects resembles figures in the patient's past. The therapist may be identified as the patient's father, for example, or, in less intense reactions, as being like the father. That is, in the early stages of the work the patient may find in the therapist aspects of earlier life relationships that may have been troublesome but that could to some extent be defined in conventional terms; in many instances the relationship with the father fits this definition. Later, as the therapeutic relationship is consolidated and established as durable, more diffuse and disturbing distortions of perception may appear, seemingly related to infantile, preverbal experiences with a mothering person. At such times the patient becomes more withdrawn and overtly psychotic.

If the patient insists that the therapist is someone other than himself, the therapist may show some impatience, indicating that the patient is grossly mistaken. If the patient says that the therapist is *like* someone else, the therapist wants to know what evidence there is for the alleged resemblance, thus opening the way for further investigation of past experience. Throughout this study of the patient's views of himself and the therapist, there is an interplay between the presentation of reality that can be consensually validated (and requires acceptance and confirmation) and distortion (that requires correction). The patient's correct estimates of a situation are encouraged, and the incorrect, anxiety-driven ones are subjects for study and modification.

In all this work, long commentaries are seldom heard or recalled by the patient, and anxiety interferes with accurate listening. Therefore, when the therapist has something to say, he should be reasonably sure that it is relevant to the patient's concerns at the moment, that it is spoken when anxiety is not so great as to prevent his being attended to, and that it is stated briefly.

The therapist. The therapist will often be unsure of himself in this work and will at times be anxious to the point of wanting to abandon it. A personal psychoanalysis is recommended for anyone who plans to do intensive psychotherapy; the experience of anxiety and the insights gained in a developing controlled interpersonal relationship can be informative about one's own therapeutic interventions. It is particularly important that the therapist not be governed by major motivational systems outside of his awareness: they may lead him into destructive behavior with his patients. The therapist should consult regularly with a colleague, presenting an account of the course of treatment and discussing the implications of what he describes. Such presentations may be embarrassing at times, but it is easier to recover from embarrassment than from serious misadventure in a treatment procedure.

In the therapy of a schizophrenic patient, the therapist experiences intense emotions that may not seem suitable to him in his role as a physician. He may feel anger, disgust, despair, rage, lust, and other sentiments that reflect past experience, the present encounter, and the increase of anxiety. He finds that he must attend to more than the verbal exchanges between himself and his patient, rediscovering modes of communication—odor, taste, and touch—that may never have been clearly in his awareness, that have been forgotten, or that seem somehow unsuitable to adult living. Often the therapist is dismayed by observing that he seems to mean nothing to his patient; despite his efforts as psychiatrist, physician, and well-intentioned, kindly human being, his patient turns from him or, worse yet, does not seem to be aware of him. In brief, the therapist often suffers from a lack of confirmatory feedback from his patient and may attempt to wring from him some indication that treatment has significance and that there is value in what is being done. All people want to be assured, on occasion, that they and their efforts are valued, but the therapist cannot rely consistently on his patient for such reassurance. When he does not find it, he should not withdraw from the situation; rather, he must continue with confidence that a human relationship, however obscure its form may appear to be, has meaning and can offer hope and a way to useful change.

There are times when therapeutic efforts miscarry, long periods of endeavor being revealed as more destructive than helpful. The therapist must face this possibility, as must any physician. He will discover

that he cannot escape the memory of his failures. He will also discover pleasure in what he does, and this pleasure he will do well to acknowledge and treasure.

Only suggestions regarding the psychotherapeutic experience with the schizophrenic person have been presented here. Each therapist must expand such an account through reading, discussions with others, and his own experiences as therapist and human being. No matter what occurs in the therapeutic venture in which he participates, the therapist is required to observe it as best he can and attempt to learn from it, refusing to be dismayed or falsely overjoyed by what he finds. In a sense, each encounter with a patient has within it the opportunity for research as well as therapy, no person being quite like another.

Suggested Cross References

In this section the nature and etiology of schizophrenia are discussed from a purely psychodynamic frame of reference. Alternate viewpoints may be found in Section 15.3 on the etiology of schizophrenia by Weiner and in Sections 15.1 and 15.4 by Lehmann. Different hypotheses regarding the etiology of infantile autism are presented by Eisenberg in his section on childhood psychosis (Section 42.1). Additional information regarding the effects of maternal deprivation and on the role of the family in psychiatry are contained in Sections 44.1 and 4.3, respectively. The author's views on the inadvisability of the use of antipsychotic medication for acute schizophrenic reactions are controversial. Alternate viewpoints regarding the use of organic treatment methods in schizophrenia may be found in Fink and Itil's section on the organic treatment of schizophrenia (Section 15.6) and in the discussions of the organic treatment modalities used in psychiatry to be found in Chapter 35.

15.6 SCHIZOPHRENIA. VI: ORGANIC THERAPY

MAX FINK, M.D.

TURAN M. ITIL, M.D.

In the absence of defined etiologies for the varieties of schizophrenia, treatment is empiric and dedicated to alleviating the patient's symptoms and reducing tensions and disturbances in the patient's family. Besides milieu therapy and psychotherapy, the organic therapies are currently used in the treatment of schizophrenia.

The organic therapies of schizophrenia have introduced optimism where isolation and incarceration existed as the principal prospects for the mentally ill less than 30 years ago. These therapies also provide a special impetus to studies of the pathophysiology of schizophrenia, with much effort being focused on the neurophysiological and neuropharmacological processes.

Although much has been learned about the role of cerebral dysfunctions in psychosis, much more has been learned about normal cerebral mechanisms. Studies in schizophrenic subjects have yielded information about the localization of functions in the limbic, frontal, and temporal lobes and the relation of neurohumors to behavior. The significance of central cerebral structures in disorders of sleep-wakefulness and vigilance and the relation of changes in scalp-recorded electroencephalograms (EEGs) to the effects of psychotropic drugs have been especially illuminating subjects of study.

The ways in which the organic therapies of schizophrenia are associated with alterations in behavior are unclear, but it is to the changes in brain function that much attention has been directed. The efficacy of organic therapies is dependent on the type, degree, and duration of the induced alterations in brain function. The changes in brain function are most readily measured in scalp-recorded electroencephalograms, as changes in dominant frequencies, amplitude, pattern, and variability.

EEG studies have recently achieved a special promi-

nence in the treatment of schizophrenia. In induced convulsions and in the psychotropic drug therapies, the EEG changes are useful indicators of the adequacy of treatment. When changes in the EEG are minimal with conventional treatments, the changes may be augmented by increasing the frequency of seizures or the dosages of drugs. Such increases may provide the changes in brain function necessary for therapeutic results.

Until specific treatment methods related to the cause of psychotic disorders are developed, these neurophysiological concepts and the EEG studies now in progress provide the most useful guideline for understanding the organic therapies of schizophrenia.

Ways to Induce Changes in Brain Function

Although the organic therapies of schizophrenia have peripheral and central nervous system components, the changes in brain function and the alterations in consciousness are the aspects receiving most study. Changes in cerebral function may be induced by many means, and pharmacological, electrical, and surgical methods that may be safely used to alter brain function have been pressed into service at one time or another.

Pharmacological agents induce relaxation or sleep (barbiturates, bromides, soporifics, anesthetics), decrease psychomotor activity with little change in consciousness (reserpine, phenothiazines, butyrophenones), or alter consciousness for prolonged periods (insulin). Some agents increase motor and mental activity (amphetamine, monoamine oxidase (MAO) inhibitors, imipramine) or induce hallucinatory states with marked changes in consciousness (atropine, scopolamine, piperidylbenzilate) or with minimal change in consciousness (lysergic acid diethylamide (LSD), psilocybin, mescaline). Some agents are used to induce seizures (intravenous pentetrazole or the inhalant, hexafluorodiethyl ether).

Electrical methods to alter brain function are used to obtain relaxation or sleep when low voltage electrical stimulation is used (electrosleep, electronarcosis) or to induce loss of consciousness and seizures as in convulsive therapy.

Surgical methods include the separation of a part of the brain, as in the operations of lobotomy, leukotomy, topectomy or orbital undercutting, and stimulation through implanted electrodes. Specific central brain structures may also be modified for prolonged periods by cautery or freezing.

The selection of a specific treatment is made difficult by the absence of suitable comparative studies and lack of knowledge about modes of action. Each method appears successful to the extent that it produces changes in brain function, the results varying with the type and duration of the induced changes. But the brain exhibits both a resistance to persistent change and an ability to recover, so most of the in-

duced changes, even after extensive treatments, may be measured for only a few days to a few weeks.

The present view is that the treatments are non-specific in the schizophrenias and that the selection should be based on prior clinical experience and the physician's attitude regarding the safety and efficacy of the various methods in each psychopathological syndrome. Since psychotropic drug therapies are generally considered safer than induced convulsions and more effective than insulin coma, atropine coma, and cerebral surgical procedures, treatments are usually prescribed in that sequence.

Indications

Although duration of illness, length of hospitalization, type of onset, previous treatment, age, social class, and educational level influence the selection of treatment, the use of organic therapies is related chiefly to the clinical diagnosis and specifically to the individual's predominant symptoms. The psychopathological symptom cluster approach is proposed in this section. As the specific techniques of treatment and usual adjuvants are described elsewhere, the treatments and daily dosages noted here are presented as guidelines.

Excitement and overactivity in acute schizophrenia. The excitement, agitation, restlessness, and hyperactivity of acute schizophrenic reactions are frequently modified by organic treatment. In mild states, sedatives and hypnotics (as barbiturates, paraldehyde, or chloral hydrate) are temporary expedients. In active states, the phenothiazines are the principal agents used, with dosages that are often high, for example, chlorpromazine, 600 to 1,200 mg.; thioridazine, 400 to 600 mg.; trifluoperazine, 20 to 50 mg.

In Europe and Canada, a wider variety of psychotropic drugs have been found efficacious and safe than are used in this country. In acute excitement states, levomepromazine (150 to 300 mg.), haloperidol (4 to 15 mg.), and prothipendyl (80 to 160 mg.) are widely used.

In severe excitement states, psychotropic compounds may be administered parenterally, with frequent applications necessary early in treatment. Dosages are often higher than in other conditions, for example, chlorpromazine or promazine, 50 to 100 mg. four times a day intramuscularly. When the state of excitement is poorly controlled by phenothiazines, concurrent electroconvulsive therapy has been applied, with the frequency of treatments varying from three times a week to three times daily.

When agitation and restlessness are prolonged and the patient is poorly responsive to these measures, a continuous state of sleep and sedation maintained by barbiturates or artificial hibernation using lytic cocktails for 1 to 4 weeks has been recommended. The subsequent administration of phenothiazines has been reported as producing a prolonged modification of the psychosis.

Disturbance of thought content and perception.

In acute reactions marked by delusions and hallucinations, as in paranoid or undifferentiated schizophrenia, the phenothiazines (particularly those of the piperazine group) and induced convulsions have been found effective. High dosages are generally not required, although the medication must be maintained beyond the period of the disappearance of symptoms.

When these states become protracted, various other treatments may be required. High doses of phenothiazines, especially butaperazine (30 to 120 mg.), perphenazine (8 to 32 mg.), and trifluoperazine (20 to 50 mg.), have been successfully applied. It is in such subjects that prolonged insulin coma therapy has been most used. In one technique, insulin is administered daily for a 2-month period, and the coma state is maintained at the level of absent corneal reflex, absent deep tendon reflexes, and miotic pupils for a minimum of 1 hour (40 to 50 comas). Comas may be interrupted by the administration of sugar (glucose) or glucagon.

There is considerable dispute as to the merit of insulin therapy, since the usual treatment differs little in clinical efficacy from chlorpromazine therapy or barbiturate sleep. Better clinical results in schizophrenia have been reported in those subjects in whom prolonged organic-type reactions have occurred during deep coma therapy.

Induced convulsions have also been recommended, but these are reported as less successful unless applied as regressive electroshock. In this treatment, grand mal seizures are induced daily with the occasional administration of two to three seizures a day, spaced at 10- to 30-minute intervals. Patients develop a confusional amnesic state, from which recovery occurs 2 to 6 weeks after the last treatment. Special claims have recently been made for the intravenous induction of seizures by hexafluorodiethyl ether or pentetrazole.

Combinations of psychotropic drugs have recently been recommended, as in the simultaneous administration of chlorpromazine (200 to 300 mg.) or thioridazine (300 to 400 mg.) with chlordiazepoxide (50 to 80 mg.).

Apathy and withdrawal in hebephrenic or simple schizophrenia. The anergic state in residual schizophrenic disorders, characterized by apathy, withdrawal, and disinterest, is often treated with piperazine phenothiazines, such as trifluoperazine, 5 to 15 mg., or butaperazine, 20 to 60 mg.

When phenothiazines with a marked sedative component are used, such as chlorpromazine and promazine, anergy and apathy may be intensified or induced. This state may be responsive to the simultaneous administration of imipramine (200 to 300 mg.) or anticholinergic agents (procyclidine, 5 to 20 mg., benzotropine, 2 to 4 mg.) while the phenothiazine treatment is continued.

Among the more novel treatment approaches now

under study in Europe is the technique of symptom provocation, which has been used in patients with chronic apathy, withdrawal, and anergy without florid symptoms. In this method, a more active psychotic process is produced by the repeated administration of imipramine (100 to 300 mg.), hallucinogens (Ditran, 5 to 15 mg., LSD, 100 to 300 μ g.), or MAO inhibitors (phenelzine, 100 mg.). When a more active psychotic state is induced, treatment is then continued with the phenothiazines or butyrophenones.

Stuporous states in catatonic schizophrenia. The posturing, rigidity, and tension of catatonic states may be reduced by such phenothiazines as high doses of chlorpromazine (600 to 1,000 mg.), thioridazine (400 to 600 mg.), trifluoperazine (20 to 50 mg.), butaperazine (30 to 120 mg.) reserpine (5 to 10 mg.), or haloperidol (10 to 30 mg.) administered parenterally. Intravenous barbiturates (as amobarbital and thiopental) or induced convulsions by chemical or inhalant methods are also occasionally successful. These agents may alleviate the acute catatonic state, but continued treatment generally requires phenothiazines or insulin coma therapy.

Catatonic excitement may be responsive to the same measures as other excitement states. Because such patients are prone to physical debilitation, tube feeding and continuous sedation may also be necessary.

Affective-emotional states. Disorders in affect and emotion often accompany pseudoneurotic or schizoaffective states. When the depressive components without agitation are in the foreground, treatment with imipramine (200 to 300 mg.) or amitriptyline (50 to 100 mg.), either alone or combined with phenothiazines (thioridazine, 200 to 300 mg., and chlorpromazine, 200 to 600 mg.) is suggested. When patients fail to respond to such combined treatment, measures similar to those described for the therapy of the anergic state are applicable.

When anxiety is prominent, induced convulsions or psychotropic drugs with marked sedative components may ameliorate the symptoms. Failure to respond is treated as described for the therapy of excitement states.

Schizophrenia with obsessional states. Severe obsessional features in schizophrenia are associated with poor prognosis. When obsessional features are prominent, high doses of piperazine phenothiazines with or without induced convulsions may be useful. Protracted obsessional states with marked tension or obsessional psychosis have been treated with cerebral surgical procedures or insulin coma.

Contraindications and Limitations

The risks in the somatic therapies are small, and there are few contraindications. Induced convulsions appear to provide an unusual cardiovascular stress, so elderly patients with cardiac disease require special care. Patients with known metabolic diseases, especially those affecting the liver, or hematological

disorders may also require special care when phenothiazines are recommended.

Secondary Effects

The side effects of induced convulsions, insulin coma, and psychosurgery are described elsewhere. Extrapyramidal symptoms, akathisia, and restlessness frequently occur with many psychotropic drugs. They are prominent with those compounds that are particularly effective in reducing florid psychotic manifestations. These symptoms are considered side effects by some authors but are also viewed as necessary accompaniments to successful treatment with present medications. These effects are readily inhibited by antiparkinsonian drugs, and the treatment of schizophrenic patients is not ordinarily interrupted because of these symptoms.

Suggested Cross References

Additional information regarding the organic treatment modalities, such as electroconvulsive therapy, the psychotropic drugs, and psychosurgery, may be found in Chapter 35 in Area G, on psychiatric treatment. Psychological treatment of schizophrenia is discussed by Will in Section 15.5.

Chapter 16

Psychotic Disorders. II: Paranoid Reactions

16.1 PARANOID REACTIONS

NORMAN A. CAMERON, M.D., PH.D.

History

Paranoia is one of the oldest terms in medical literature, dating back at least 2,000 years to the ancient Greeks. By *paranoia*, which could be translated as "thinking beside oneself," they meant something equivalent to our lay and legal term "insanity." It seems to have disappeared from the literature around the 2nd century, A.D. For a while in the 18th century it was revived and enjoyed a short-lived popularity as a class name for delirious and delusional disorders. When Pinel reformed the then florid Linnean nomenclature of psychiatry shortly after the French Revolution, the term "paranoia" again became current, especially among those following Heinroth's classification in 1818.

Heinroth followed the influential philosopher Kant in dividing mental disturbances into those of the intellect, those of the will, and those of the feelings. Paranoia he regarded as essentially a disorder of the intellect. This attitude has its parallel today in psychiatrists who speak of "thinking disorders" in paranoia, paranoid states, and paranoid schizophrenia. Heinroth also introduced the term *Verrücktheit* into German psychiatry, where it is still often used as the equivalent of what we call paranoia.

Kahlbaum in the latter third of the 19th century also made use of the Greek term paranoia but in a much more definitive way to signify a delusional state. Kraepelin gave to paranoia its present precise formulation, reserving the term for cases of chronic, highly systematized, incurable delusions but without general personality deterioration. This conception applies clinically to an extremely rare syndrome. Kraepelin also recognized the existence of paranoid personalities.

Unfortunately, Kraepelin confused the situation greatly by including a large section, entitled *Die Paranoiden Verblödungen (Paraphrenien)*, alongside his famous section on dementia praecox under the

general heading of "endogenous deterioration." It is said that he intended paraphrenia to lie midway between paranoia and dementia praecox or schizophrenia, but there is nothing in his four-volume eighth edition of *Psychiatrie* to support this belief. Meanwhile, Bleuler, in 1911, published his monograph *Dementia Praecox or the Group of Schizophrenias*. Bleuler gave a definite and important place to the group of paranoid schizophrenias; but, naturally, he did not allude here to paranoia or paranoid states.

Another line of development began with Freud, who in 1896 described a case of paranoia as being the product of a defense mechanism. He thus departed both from the Kantian philosophy and from the descriptive Kraepelinian psychiatry to place paranoia on a par with hysteria and obsessions. He conceived of the principal paranoid defense as projection, that is, the rejection from consciousness of some intolerable accusation against oneself, originating in one's own unconscious, and the localization of it among other persons, known or unknown. This, even today, seems not merely to describe what we see happening in persons who become paranoid, but to make their delusional misinterpretations intelligible. It places paranoid delusions close enough to the misinterpretations of every day life and to the ancient, universal practices of finding scapegoats to make it seem worthwhile to study and work with the paranoid human being, instead of merely labeling him. Fifteen years later, Freud followed up this early study with an analysis of the autobiography written by an eminent jurist, Daniel Paul Schreber. Freud called Schreber's disorder "Dementia paranoides"; but today it is considered to have been a florid case of paranoid schizophrenia. Nonetheless, Freud's brilliant interpretation of the paranoid components has since held the major attention of psychiatrists.

Early in the century, Adolf Meyer, working no less courageously but on a more descriptive level, stressed that paranoiacs seem incapable of adapting their thinking to the consensus; they try rather to bend objective reality to accord with their delusional thinking. He emphasized that they are excessively concerned about what others think of them and that they show a progressive inability to validate or invalidate

their suspicions or to correct their conclusions in personal matters.

Bleuler came out with a second edition of an earlier monograph that, in sharp contrast to the first edition, showed the influence of Freud—who gave seminars at Bleuler's clinic—in clearly relating paranoia to affectivity. He insisted, however, on the basis of a lifetime of experience, that paranoid developments are not matters of impulse but occur only in certain kinds of persons. He did point out that ordinary errors and misinterpretations are related to delusions.

Kretschmer in 1927 delineated a hypersensitive characterological type of person with strong tendencies to self-reverence. He considered such persons especially vulnerable to paranoia and paranoid developments. Cameron in 1943 ascribed the origin of both the hypersensitive, asocial person and the development of paranoid delusions to a failure of the person in childhood to acquire minimal social skill in role taking and especially to an inability to take the perspectives of other persons for the practical purpose of comparing these consensual perspectives with his own. Later experience led him to the concept of the pseudocommunity and its probable relationship to a failure in early life to develop basic trust.

Although nearly all modern conceptions of paranoid developments emphasize the personal environment of the disturbed individual, none of them assumes that there may not be congenital differences among infants that render some more susceptible to such failures than others.

Definitions

The Committee on Nomenclature and Statistics of the American Psychiatric Association grouped paranoia and paranoid states (or paranoid reactions) as psychoses without known brain pathology. It defined them as cases showing persistent delusions, generally persecutory or grandiose, and ordinarily without hallucinations. Emotional responses and behavior are consistent with the ideas held. Intelligence is well preserved. This category, the Committee went on, does not include those reactions properly classifiable under schizophrenic reaction, paranoid type.

The Committee stated that paranoia is extremely rare and is characterized by an intricate, complex, and slowly developing paranoid system, often logically elaborated after a false interpretation of an actual occurrence. The patient frequently considers himself endowed with superior or unique abilities. The paranoid system is practically isolated from much of the normal stream of consciousness. There are usually no hallucinations. The personality is relatively intact and remains preserved in spite of a chronic and prolonged course.

The Committee defined paranoid state, which is usually called paranoid reaction in the current literature, as characterized by delusions. It lacks the logical nature and systematization seen in paranoia, yet it

does not manifest the bizarre fragmentation and deterioration of schizophrenic reactions. It is likely to be of short duration, although it may be persistent and chronic.

The Committee did not recognize or include the paraphrenias, although sometimes one still meets this term in the literature. In the early 19th century, Guislain used paraphrenia synonymously with folly, and both appear to have been equivalent to our modern concept of schizophrenia. Kraepelin used it in a special sense, as intermediate between paranoia and schizophrenia. With his usual flare for subdivision, he described four kinds of paraphrenia. Freud occasionally used paraphrenia as an equivalent of schizophrenia. Hinsie and Campbell stated that its most common usage is "to denote a disorder characterized by phantastic, absurd, paralogical delusions without deterioration, dementia, or loss of contact with reality except in the area of the delusional system." There seems to be no good reason for retaining paraphrenia within our nosological system.

What has just been said about the paraphrenias applies with even greater emphasis to what the older psychiatrists called monomanias. A century ago, paranoia was occasionally called intellectual monomania, and in such a designation the old time Kantian distinctions of intellect, will, and affect come clearly through. Intellectual monomania has no place in modern psychiatric thought.

Epidemiology

There are no reliable statistics concerning the incidence of paranoia and paranoid reactions. Classical paranoia, as defined by the Committee on Nomenclature and Statistics of the American Psychiatric Association, is extremely rare. Tyhurst, using Miller's tables, found that paranoia and paranoid conditions together make up about 10 per cent of hospital admissions. There seems to be no good evidence of an age distribution. Tyhurst thinks that hospital admissions represent more the age at which paranoid reactions become intolerable to others than the age at which they begin to be recognizable.

Earlier evidence that paranoid reactions seemed to be commoner among males than females has been contradicted by more recent statistics indicating that the female incidence is more than twice that of males. As to marital status, delusional psychoses appear in hospitalized patients more frequently among divorced or separated individuals. This may represent an intolerance of the intimate relationship involved in marriage, but there is no reliable evidence to justify this conclusion. The same reservations must apply to conclusions regarding education, socioeconomic status, and religion. There may be significant differences, but we do not have reliable evidence of them yet.

There is some evidence that more persons with paranoid reactions come from urban than from rural areas. This may be because in the country it is easier

to get away from other human beings than in a city. To a certain degree, there is a greater tolerance for oddities in rural than in urban areas, particularly for the hypersensitivity and threatened aggression that many people display during a paranoid episode. A man may go armed with a rifle and be prepared to shoot to protect his lawful rights to his share of irrigation in the wilds of New Mexico. No one could do the same thing in a city. The fact that no one intends to cheat this man of his irrigation rights does not seem to affect the neighboring people. That is simply the way he is. Nobody interferes. Nobody wants to interfere.

There is also some evidence that paranoid reactions are more common among migratory and immigrant groups than among the more permanent or resident population. Even severe paranoid reactions may disappear when a paranoid immigrant is returned to his own country. Migratory workers and minority groups, of course, have no such choice; they are living in their own country. A spontaneous hostile attitude toward migratory workers and minority groups seems to be near the surface, even in the absence of trespass or violence, not only in the United States but almost everywhere. It seems to come from some biological origins like those that make ants from one nest senselessly slaughter inoffensive ants from some other nest, which they have been doing for millions of years. It is often overlooked, for example, that the fate of the gypsies in Nazi Germany was as savage as that of the Jews, even though neither was plotting treason against the state. They were simply identifiable minorities.

Reliable statistics with regard to the incidence of paranoid reactions may be lacking because the reactions are often regarded as justified and reasonable, even to normal persons; therefore, a paranoid person may not seek or get the help he needs. There have been many instances in which a paranoid person, and occasionally a severely paranoid person, has succeeded in convincing judges or juries that his delusions are fact.

A great many persons experiencing a paranoid reaction have always had unusual difficulties in making close, meaningful relations with other persons. They anticipate that they will have the same difficulty with a therapist, as a rule correctly, and they are not venturesome enough to make the attempt to seek help. They sweat it out alone, join some movement, or move away—escaping both therapeutic assistance and the statistics.

Etiology

Biological inheritance appears to play no part in the development of paranoid reactions. One review of 400 hospitalized patients with paranoid reactions revealed that paranoid trends were present in only eight ancestors. A person who, as an adult, develops a paranoid reaction, may never have been regarded as

having a paranoid personality. However, it can be assumed that, for some reason, he has developed a predisposition to mistrust others and to project on to these others his own feelings whenever he is under stress. He is presumably more vulnerable to this kind of defensive maneuver, disowning projection, than to other forms.

Nor are there any known neuropathological bases or neuropathological concomitants of paranoid reactions. The exaggerated usage of the defenses of denial and projection in paranoid reactions suggests a distortion of early childhood development, but this seems to be related to the family structure of which the patient has been a part rather than to his own neurophysiology.

Paranoid reactions and homosexuality. Freud developed the thesis that paranoia arises when homosexual trends escape repression. It has for a long time been taken for granted that a person developing a paranoid reaction is basically homosexual and that his homosexuality arises from a fear of castration. Nevertheless, when the clinical evidence is examined, difficulties arise concerning these assumptions.

In the first place, Freud's key patients would unquestionably be regarded today as schizophrenic. The most famous of these, and probably the most famous case in all of psychiatric history, was that of the gifted jurist Daniel Paul Schreber. This remarkable man wrote an autobiography, *Memoirs of My Nervous Illness*, in which he described his imaginary transformation from a man into a woman. One interesting thing about Schreber was that he made no attempt to repress his homosexual aspirations. Rather, he made them into a kind of religion, albeit a glorified and personal religion. Although Freud had no contact with Schreber, who was the patient of the famous neurologist Flechsig, he studied Schreber's autobiography and made a masterful analysis of its paranoid contents. Freud's conclusion from this study and from his own and his colleagues' experiences was that paranoid reactions and homosexuality were inseparable.

However, clinical evidence within the past 40 years has not consistently supported Freud's thesis. It is perhaps fitting that most of the clinical reports include hallucinating paranoid schizophrenic patients, since this is what Schreber certainly was himself. Such clinical reports have come from persons within the American Psychoanalytic Association (like Henrietta Klein) and from persons outside it. They simply state the fact that clinically one does not find paranoid reactions necessarily related to homosexuality. As a matter of fact, Schreber's case is a far cry from contemporary views of paranoid reactions.

W. G. Niederland succeeded in uncovering some of the old writings of Schreber's father, Dr. D. G. M. Schreber. He was apparently a very well known health educator as well as a physician. This health educator father seems to have been an unconscious

sadist. He invented all kinds of rigid physical restraining devices to be worn by boys and girls as they studied. In his many books, the elder Schreber described these various artifices of his in terms of improving children, but the illustrations, some of which Niederland has reproduced, make it abundantly clear that they must have made the helpless child feel exceedingly uncomfortable. There is also evidence that the elder Schreber was a forceful, overpowering man who ran an orthopedic institution, where the younger Schreber had to live out his childhood. It is inconceivable that the younger Schreber could have escaped the wearing of his father's contrivances.

Niederland and others have called attention to the many similarities of terminology in the elder Schreber's books on health education and his psychotic paranoid son's account of his own psychosis in his *Memoirs of My Nervous Illness*. Some of these similarities have helped to clear up previous obscurities in the younger Schreber's account. Schreber's memoirs, which have been translated into English, are strongly recommended as probably the best and most complete autobiography of a psychosis in the literature. Niederland's papers are likewise recommended, as is a symposium held in 1962, organized by Kitay, and participated in by Niederland.

A great number of overtly homosexual persons never develop paranoid delusions, and a great many persons are paranoid without being homosexually oriented. It is easy enough to dismiss such clinical material with the challenge that at least latent homosexuality can be demonstrated in persons who develop paranoid reactions. But latent homosexuality is far more widely distributed than are paranoid reactions. There may be some relationship between the two; but, as Klaf et al. indicate, the relationship does not appear to be a causal one.

Quite aside from clinical findings, the deep emotional relationships normally existing between fathers and sons, between mothers and daughters, between like-sexed siblings, like-sexed chums, and like-sexed friends must be considered. These cannot be simply lumped together as homosexual. They are part of the foundation of identification and are therefore at the very basis of growing a normal personality and a normal sex identity. They are not merely the bases of paranoid reactions.

Basic trust deficiency. Patients who develop paranoid reactions are probably persons who in early childhood were unsuccessful in developing basic trust. This is, in effect, a basic confidence, derived from innumerable experiences during infancy and early childhood, that, whenever one's frustration becomes intolerable, someone will relieve it and thus restore a tolerable equilibrium. The importance of such basic trust or basic confidence becomes immediately apparent when it is considered how completely helpless the infant or very young child is unless someone else reliably helps him.

In order to understand how a paranoid reaction can develop, one must understand that even the most normal person lives on trust. He must take action continually on the basis of fragmentary information, which only later events can confirm or contradict. A person must assume all the time, without confirmation, that people in general are well disposed toward him or at the very least that they will avoid harming him to the best of their ability.

The normal, everyday person hears parts of a sentence or sees fragments of behavior around him and assumes that what he misses will not put him in personal jeopardy. He eats his meals without thinking that his food may be poisoned. He works during the day, relaxes afterward at home, and then allows himself to go to sleep, without feeling it necessary to take even the most elementary precautions against being injured or destroyed.

When it comes to emotionally charged matters, however, the picture changes, even among quite normal persons. There is in everyone always an undercurrent of magical and superstitious thinking that is not released except in dreams, and even then it is almost always forgotten. In short, we all live deeply irrational lives; but we have all been schooled in childhood to develop an overlay of realistic, logical thinking and a relatively impersonal attitude even about deeply personal matters.

Clinical Description

It is customary to distinguish four kinds of paranoid reactions: (1) jealous, (2) erotic, (3) grandiose, and (4) persecutory. Of these four subdivisions, the persecutory is clinically by far the most frequent and most important variety.

Paranoid jealousy. The jealousy one sees in paranoid reactions is no different from normal jealousy, except that it is much more profound and more relentless. Paranoid jealousy is seldom without some objective, external reason. What makes it pathological is that it rests on evidence that seems inadequate to the normal person. Nevertheless, the reasons for jealousy that the paranoid person gives seem to him sufficient to support his belief. But what he believes is actually a projection of his own wishes and desires, which he denies as his own.

Paranoid eroticism. It is easily perceived that the eroticism of the paranoid person is a denial of his own desires and a projection of these desires upon another person. This other person may be someone the patient actually perceives, however incorrectly, as the object of his passion. It may also be someone imagined.

Paranoid grandiosity. This seems to represent a phase of infantile or early childhood development in which the infant or child conceives himself as having tremendous powers or abilities. Regression to such a phase, in the face of frustration, places the paranoid person in the imagined position of an omnipotent person, whose powers cannot be diminished or denied.

Persecutory paranoid reaction. The most outstanding characteristics of persons who develop a psychotic persecutory paranoid reaction are a deep distrust of others and an unusually strong tendency to deny their own hostility. They characteristically project their hostility on to other persons. Such persons may or may not have had a recognizable paranoid personality before they were exposed to stressful conditions, to real or imagined danger, or to actual damaging discrimination or imagined discrimination.

From time to time, whole communities seem to respond to real or imagined threat with something approaching paranoid panic. The invasion from Mars broadcast in 1938 brought hundreds of people who had not heard the introduction which explained that it was just a play, on to the roads with all their movable possessions loaded on to pushcarts and in automobiles. And a rumor in a Midwestern town that a deadly gas was being disseminated aroused a paranoid panic in a high percentage of the population. In these instances, the reactions were too general to be dismissed as simply a widespread paranoid personality. They showed a widespread belief in the unlikely danger and a tendency to flee, even when people were actually safe where they were.

The preliminary threat. An upsurge of overwhelming fear of retaliation may immediately follow one's own upsurge of overt hostility. This fear, however unreasonable it may be, is actually the fear of one's own conscience or superego or of some regressive antecedent of one's mature superego. To deny the internal sources of conscience or superego is a serious matter. If a person denies the threats of his own conscience or superego, he is left with only one resource, and that is to look for the threat in his environment.

This is the essential nature of what it means to project. The patient finds his own hostility in other persons, who now seem to threaten him. Thus, what appears to *produce* a persecutory paranoid reaction is really that which tips a chronically unstable balance. In the past the patient has maintained this unstable balance through successful denial and projection or disowning projection. Disowning projection in the infant is later normally subordinated to adequate repression.

From what happens clinically in persecutory paranoid reactions, one has to conclude that repression has all along been inadequate. In other words, there has been too much dependence upon denial and projection or disowning projection. This is the heart of the matter. In an emergency, these relatively infantile defenses take over and become predominant. A psychotic paranoid reaction then appears. It is probable, although not experimentally proved, that adults who develop paranoid reactions under stress have not been able to form or have not been given the necessary intimate close relationship with a loving mother or mother substitute.

Onset. The onset of paranoid delusions of persecu-

tion typically occurs in a setting of environmental or interpersonal stress. It is generally believed that this happens most often in adults who have habitually found fault with everyone but themselves and whose accusations against their acquaintances sound very much like vignettes of themselves. The same kind of thing occurs less benignly when a paranoid person begins by expressing open distrust, suspicion, hostility, and self-reference, although these attitudes appear unjustified to his friends and relatives. If they oppose him or try reasoning with him, they are likely to become frightened by him, especially if he reacts by accusing them of also being parties to his fantasied persecution, which paranoid patients often do. The major defect of the paranoid reaction, under these circumstances, is to isolate and estrange the patient at the very moment when he needs someone to confide in and to help him.

The onset of a paranoid reaction may be sudden. In that case it represents the sudden breakdown of an adaptive and defensive system that had previously been adequate for all ordinary practical purposes. Often, however, the suddenness is only apparent. The abrupt failure in such cases is analogous to many cases of sudden cardiac decompensation. There have been many indications in the recent past that stresses were not being well handled; but the persons who noticed these indications maintained an unjustified confidence that the situation was only something temporary and would clear up by itself.

The precipitating situation in a paranoid psychosis may seem trivial to persons who have maintained faith in the patient's intrinsic ability to deal with increased stress. This misplaced confidence has been concealing the patient's actual situation from those close to him. In these situations, a psychotic development may proceed behind a facade of apparent health, until the patient is no longer able to control his impulses or conceal his illness. When this point is reached, the open manifestations of paranoid psychosis may indeed appear abruptly, even though they have been going through a relatively slow internal evolution for some time.

Early phases. A more or less prolonged prodromal phase is common in paranoid reactions, whether it is recognized or not. The patient meets with frustration, rebuff, threat, loss, or temptation—as, of course anyone else might. The difference is that, having no one he can trust and confide in, he reacts by first withdrawing his interest in his environment and then by losing interest in it. Sensory or perceptual isolation may have an extraordinary effect on supposedly normal subjects who voluntarily agree to their isolation but who are given to understand that they can end it whenever they want to. Some of these subjects find their isolation so unendurable that they quickly end it. The paranoid person is not isolated in the same sense, but he feels himself cut off from all meaningful human interactions when he most needs them.

The paranoid patient becomes preoccupied and, like any other isolated person, he undergoes regression. In his regression and isolation he tries to understand what has happened to him. This leads him to try once more to regain contact with objective or consensual reality, with the reality that other people seem to be living in. But because he cannot change his delusional beliefs, he must reconstruct the realities around him in such a way that his delusions appear confirmed. The world he now lives in is definitely and personally a dangerous world.

This apparent confirmation of the patient's delusional beliefs greatly increases his anxiety. To him, things seem somehow changed. He himself feels somehow different, estranged, puzzled. He tries to account for the changes that he observes in terms of his surroundings, whereas the origins of the changes lie within him. The result is that his growing anxiety, coming from within him, is projected and appears as a growing danger from his surroundings.

The paranoid patient becomes, as anyone in objective danger becomes, watchful and uneasy, uncertain of what is going on around him. The more his suspicions and misgivings increase, the more he examines—distrustfully—his environment. And the greater his suspicions and misgivings, the less he can depend on anyone but himself to investigate the situation. Unfortunately for him, he has always depended on solitary observation; he has always looked for and found hidden meanings; he has always depended on the use of leading questions and the search for hidden clues.

The more a person with these attitudes and habitual techniques examines any situation, the more likely he is to conclude that "something is going on"—something of personal importance that eludes him. When he reaches this, usually early, conclusion, he begins to notice many things that had previously escaped him. People seem to give meaningful glances in his direction; they gesture, smile, laugh, make facial expressions, and even perform unexpected movements or assume special postures for his notice.

In the preoccupied, regressed, and uncertain state of things the patient now experiences, everything seems somehow meaningful and related to him, even though he cannot seem to grasp the significance of what is going on. This self-reference has led some workers in the field to assume that centrality is the major factor in paranoid developments; that is, the paranoid person feels himself the center of attention. There is a certain amount of truth to this. The man who feels the major object of a murderous pseudo-community is without doubt making himself the center of attention. It has often been noted in the psychiatric literature that many paranoid persons would rather be the object of attack than not be noticed. This, however, is not a constant finding. Paranoid patients often feel themselves to be just part of some great design. And many narcissistic patients want to be the center of attention but are not paranoid.

The psychotic paranoid patient does not understand that his rising anxiety comes from processes within himself, not from rising environmental dangers. He does not realize that, in the very process of withdrawing from objective reality and regressing, he has unwittingly precipitated the estrangement he now experiences, the puzzlement about what is going on around him, or the imminent threat of a breakthrough of his own unconscious impulses, which he had until then been able to contain through strong processes of denial and projection, which assisted his weak repression.

Even a normal person will find that, the more fearful and watchful he becomes, the more dangerous his surroundings appear. To a fearful, suspicious, vigilant, anxious paranoid person, everything around him seems to justify and reinforce his distrust. His human environment appears to be conspiring to make him uneasy and on guard. He finds things at home or at work purposefully disarranged, as if to test his vigilance or his intelligence. In the street he finds himself jostled, pushed, obstructed, or ridiculed. He misinterprets innocent laughter as something malevolently directed at him. People appear to be talking about him in a depreciating or slandering way. Someone smiles at someone else, and the patient can only conclude that they are smiling about him. All the time, the plot is thickening, the mystery seems to grow and grow. The patient's need for some explanation of all that is going on becomes irresistible.

Preliminary crystallizations: finding a focus. Even a normal person could not endure as much anxiety, as much uncertainty, as much instability as this without seeking an explanation. It is characteristically human to look for explanations, for some kind of hypothesis under which whatever appears strange may be subsumed. Without some kind of preliminary crystallization, some guess as to what lies behind what one is experiencing, a person may be held in intolerable suspense.

Paranoid reactions involve a great deal of anxiety. Once paranoid suspicions have been aroused, they have to be dealt with. Even a mistaken conclusion seems more comforting than no conclusion at all. Unfortunately, the person developing a paranoid reaction is one who has much less than average ability to judge reality. He is typically a person who has little skill in taking the role of others, of putting himself in their place and looking at his own situation with at least passable objectivity. He has had little experience in confiding in other persons, and he does not communicate readily, no matter how much he needs to do so.

A paranoid person developing active delusions of persecution cannot simply give up the denials and projections or the disowning projections that make up his delusions. If he tried to do this, he would be overwhelmed by the hostility they express. His delusions defend him against his own hostility. If he were to

recognize and accept his own hostility, it might be sufficient to destroy him, as psychotic depressive hostility sometimes destroys the patient by suicide. The paranoid patient's only hope, at this phase, is that he may be able to reconstruct reality to include his delusions and still give it some degree of stability. He must find a place for his delusions in his reconstructed reality because they are defensive in nature; they help him preserve his own personality structure and protect him from suicide.

During the phases of preliminary crystallization, the paranoid patient has not yet established a master mind or a master plot. He does feel that, for some reason he does not understand, he has been chosen to fulfill some role, which he does not understand either. To him, it seems that he is being subjected to all kinds of tests, that he is being made to seem stupid, or that somehow he is the victim of some expression of contempt. For example, magazines are left lying open for him to observe, to indicate that he is considered a criminal, a pervert, or a fool. From time to time, he notices that food he is given tastes peculiar; he wonders what has been put into it. The feedback from his own hostility may make him feel that automobiles are aimed at him with the deliberate attempt to run him down.

A person developing a persecutory paranoid reaction usually begins at this time to feel that he is being systematically watched. When he steps out of his office, he notices a furtive person slink by who seems to have been keeping tabs on him. When he telephones, inexplicable things begin to happen: he dials one number and gets another, or people ring him up and then remain completely silent when he answers. At this point, he may poke around his office and his home to see if he is being bugged. When he turns to television, he hears things and sees things that seem to refer to him, matters he had never before thought were public knowledge. The same is true when he goes to the movies. Whatever this is that is going on seems to be spreading. The patient feels that he is getting more and more involved in something important that he does not understand.

It is inevitable that anyone so beset should try to communicate with someone else about all these things going on. The difficulty is that the patient has already concluded that he is being persecuted. If he tries to communicate all this to someone, his listener is almost sure to express his doubts. Since the listener does not share the patient's projected hostility and fear, he is likely to expostulate and confront the patient with realistic evidence that he is wrong. This is a mistake. To the patient, his own interpretations are so self-evident that only an idiot or an enemy could possibly doubt them. An enemy? Yes, the paranoid patient is on the lookout for enemies, and now he can only conclude that the man he has just confided in is among his enemies. The man does not believe the patient.

Therefore, he is trying to deceive him, so as to make the patient an easier prey.

Final crystallization: the paranoid pseudocommunity. In the phase immediately preceding this one, the patient has remained in suspense, perplexed, feeling that something ominous was going on but unable to recognize what that something might be. Up to now, he has failed to reconstruct his own reality, to take the place of the reality he lost when he regressed. He has failed to explain his uneradicable suspicions. He may already feel that "they" are planning something, plotting something against him. But he can say neither what that something is nor who they are who plot against him. The final step in a paranoid reaction is to find answers for these questions: who "they" are and what they are up to. It is this step that leads to the formation of a pseudocommunity, a group of real and imagined persons bent on destroying the patient's reputation or his life.

Such a delusional organization is called a pseudocommunity because the real and imagined persons making it up are not, in fact, united against the patient at all. The "they" the patient conjures up have no factual existence, and there is, in fact, no plot against him. Like a manifest dream, the pseudocommunity is the patient's own construction. It seems dangerous or even murderous because he has denied and projected into this fantasy his own hostility, which he can no longer manage in any other way.

The paranoid person's hostility has escaped repression. It is now accessible to his preconscious thinking. Therefore, he must deny it and project it, since he can no longer repress it. The persons on whom the patient is most likely to project his irrepressible hostility are usually authoritarian figures or competitors who, he believes, are only disguising evil designs behind a show of friendliness.

The pseudocommunity may be defined as an imaginary organization of real and imagined persons who seem to be united in some plot against the paranoid patient. The alleged plot is actually an organization of the patient's own hostility, which, somewhat in the manner of the director of a play, he allots to specific persons or agencies around him. His story, if he confides it to anyone, sounds like a mystery story. It is, however, a dangerous story because the patient may at any time take action against any of his unsuspecting persecutors.

This crystallization of a pseudocommunity from the obscure hostility, fears, and suspicions preceding it confers upon the paranoid patient a certainty that, for the first time, he understands what is going on around him. He thus replaces the confusion of his newly unrepressed hostility, suspicion, and fear with the clarity of a delusional reality. One of the most common statements of such a patient when he has finally constructed his delusional pseudocommunity of plotters is: "Now everything has become clear to me!"

This experience is called sudden clarification. It is not, of course, a genuine clarification. It is only a false crystallization of the patient's own denied and projected hostility. But, once a paranoid patient achieves such a false crystallization, he interprets everything in its terms. In this way, whatever actually happens around the patient seems only to confirm and strengthen his misinterpretations.

Paranoid action. A paranoid person who feels that he is being persecuted will take measures similar to those that a normal person might take when he is actually being persecuted. Paranoid action seems unintelligible to others only because they do not understand what lies behind it. Paranoid action may consist of nothing more than increased aloofness and expressions of distrust and resentment toward persons around the patient. The relation of this reaction to an early childhood failure to develop basic trust is obvious. It is, of course, a self-defeating reaction, but this is true of most psychopathological behavior. The paranoid patient occasionally shows outbursts of acute anger or bitterness. This makes other people avoid him, thus increasing his loneliness and in some instances leading to the development of an over-all paranoid personality.

A minority of persons who develop delusions of persecution openly take steps to retaliate. Such steps may at first be confined to complaints to authorities: the foreman, the manager, the police. In fortunate cases the complaints lead paranoid patients to psychiatric help. Paranoid hostility and suspiciousness, however, may extend to *all* authoritarian figures. If a paranoid patient feels that he can trust no one, he may decide impulsively to flee from the pseudocommunity or to attack someone within it. Neither action can lead to success. There is no organization that actually corresponds to the patient's pseudocommunity. He cannot solve his problems by fleeing from this nonexistent organization. If he decides to flee, he finds that he cannot escape his own projected hostility. If he makes accusations against his supposed persecutors or tries to attack them, he only magnifies his difficulties.

Adult aggression stimulates adult counter-aggression. When a paranoid person attempts aggression against any of his supposed persecutors, he meets counter-aggression. He himself is attacked and he may be forcibly restrained and confined. When such things happen to an aggressive paranoid person, who, of course, is also already frightened by his own projected threats, they seem to him to be realistic confirmations of his delusional expectations of unjustified attack by the pseudocommunity or at least by persons egged on by members of the pseudocommunity.

Fortunately, the majority of persons developing paranoid reactions do not take overt aggressive action that leads to counter-aggression, restraint, or confinement. Either they manage to live with their anxieties and suspicions until these quiet down or they seek

out-patient help that is neither threatening nor confining.

Differential Diagnosis

Most experienced clinicians report the great difficulties one encounters in trying to make a differential diagnosis in this form of disturbance or distortion. In the first place, the mechanisms of denial and projection are used to some extent by everyone; they are, therefore, carried over by anyone who develops any psychiatric disturbance. That is, the clinician can expect at least *some* paranoid contamination in the course of practically any illness, whether this be psychiatric disturbance, somatic illness, or bodily injury. In the second place, paranoia, paranoid states, paranoid reactions, and paranoid schizophrenia shade over, one into the other, as is usually the case in classification, so that often a clear cut distinction cannot be made.

The extreme, classical paranoia does not present diagnostic difficulties, especially when it is a chronic condition.

Paranoid states can be distinguished from paranoid reactions by the fact that they are, in effect, mild forms of paranoia that are actually static. They often begin as active paranoid reactions, lose their vigor and progression, and leave the person chronically paranoid, that is, delusional in some respects, which may or may not incapacitate him.

Paranoid reactions can be distinguished from paranoid schizophrenia by the absence of hallucinations, which are characteristic of schizophrenia, and by their better organization. The delusions of schizophrenia are usually fragmented, bizarre, or weird. They are much more at variance with the structure and content of normal beliefs than are the delusions of paranoid reactions or paranoid states.

When paranoid reactions develop late in life, as in paranoid involutional psychosis, they are likely to show overt or covert hostility. Unfortunately, the situation of the aging person is likely to be one of dependence, where before he had been independent, and those with whom he now lives and on whom he is now dependent may resent his presence and belittle him. His paranoid delusions, while often exaggerated, are in such cases based on actual experiences in objective reality. They also reflect the patient's realistic but exaggerated fear of death, as, for example, the not uncommon delusions of the approaching end of the world.

An acute manic episode may be mistaken for an acute paranoid reaction. This is especially likely when, instead of manic exaltation, the manic person breaks out with hostile aggression, becomes haughty, and complains widely about the way he is treated. The difference is that the manic patient is governed by his angry mood; when this passes, as it almost always does, his haughty, complaining, hostile behavior disappears. Another difference frequently observed is that

a manic patient is rather easily distracted and even sometimes led, whereas the patient with a paranoid reaction is more likely to retain an angry initiative.

What is usually called a paranoid personality varies from an irritable, hypersensitive, more or less delusional approach to other persons and to life (which seems to have been present throughout adult life and often throughout adolescence as well), to the same syndrome following some frightening, humiliating, or deeply disappointing experience. In the latter instance, it can as well be called a chronic paranoid state as a paranoid personality. In either, the person may, with perhaps some psychiatric help from time to time, lead a fairly normal life, outside of institutions.

The symptomatic paranoid states are secondary or incidental to many organic syndromes. These are no different in clinical form from the paranoid reactions; they develop in acute, including delirious, brain diseases, and they often appear as part of the symptomatology of chronic brain diseases. But to say this is to tell only part of the story.

The brain, like any other organ in the body, is dependent for its normal function on a free flow of blood through it and, in some cases, on an adequate lymphatic drainage as well. It stands to reason that anything interfering with such function will quickly lead to an incompetent brain. Thus, in many systemic disturbances, there will be incompetent brain functioning, and in many of these, paranoid reactions may arise. This is presumably because a realistic grasp of what is going on around and within oneself demands brain competence. This is frequently seen in arteriosclerotic brain disease, where the sclerosed arteries cannot supply the brain with the rather large and continuous supplies it needs. It is also seen in senile brain disease, where, in addition to sclerosed arteries, there is an actual disappearance of millions of brain cells. The surprising thing is that there does not seem to be any direct relationship between the *amount* of brain cell disappearance and the degree of cerebral incompetence.

Such general disturbances as uremia and the introduction into the circulation of such toxins as carbon monoxide, the latter sometimes in suicidal attempts, may so damage the brain that it is no longer capable of dealing realistically with the surroundings or with the rest of the person but is still capable of organizing paranoid delusions to replace reality. In all organic brain disease that is chronic or sufficiently destructive, the best one can hope for is management of the person—whether at home, in a nursing home, or in a hospital—so that he is adequately nourished and clothed and so that he does himself and others no harm.

Prognosis

Classical full blown paranoia is by definition incurable. As a matter of clinical experience, it has been

found that almost no patient in this group ever improves.

As for paranoid reactions that have come to a standstill, with the delusions still active but the general personality intact (sometimes called paranoid states), the prognosis is also very poor. The question of hospitalization is entirely one of whether or not the immediate family and the community can tolerate a person in their midst with fixed delusional beliefs. If these delusions are erotic or grandiose, they are likely to be tolerated. The same is true of the litigious paranoid person, provided there are funds always available for lawyers and court fees, since these patients seldom win their cases and are notoriously persistent in their attempts. Paranoid delusions of persecution or jealousy that become static are another matter. The person having them is nearly always a danger to someone or to society; he is, in addition, usually an unpleasant person to have around. Some such individuals find themselves most comfortable in solitude. A few are able to channel their aggression into an acceptable social movement or into a form of work that demands unpleasant aggression.

As for the acute paranoid reaction, whatever its form, it is usually amenable to therapy, provided the therapist maintains his distance and is never for a moment dishonest or discriminatory with the patient. Often, in out-patient clinics or office practice, the patient with an acute paranoid reaction makes rapid progress once he has convinced himself that he is dealing with a neutral therapist who is thoroughly reliable. Such a therapist may be the paranoid patient's first contact with someone he can trust. The course may be long, or it may be quite fleeting, depending on how well the therapist does and how well the patient can profit by the situation.

Therapy

Psychotherapy in an out-patient clinic or in the private offices of a well trained psychiatrist is by far the best approach to paranoid reactions. Although there are today many enthusiasts of hypnosis, as there were in the 1880's and 1890's, it is actually a hazardous form of therapy for these patients. They are abnormally suspicious of anything that smacks of thought control, except for the amorous female, and she is likely to have her own fantasies as to what went on during the hypnotic state. Much the same is true of drugs, which may become incorporated into the patient's paranoid fantasies.

The classical paranoiac, with an established system of fixed delusions, does best when he is not confined at all. The exception to this, of course, is the paranoiac who is determined at all costs to set right something his delusional system tells him is wrong. It is not always easy to distinguish the dangerous from the harmless paranoiac.

What has been said about the paranoiac applies equally well to patients with paranoid reactions. Some

of these reach a certain point in their delusional development and then seem to stop—the ones whose disorder many call paranoid state. It is possible, even with the apparently static paranoid person, to help him change his delusional points of view or at least to channel them into some socially acceptable movement.

Fundamentally, what the patient suffering a paranoid disorder needs most is understanding without condescension. Almost all paranoid persons are distrustful of others, usually because significant individuals in their immediate and remote past have let them down, over and over, time and again. They were not given the usual opportunities as infants to develop what Erikson has called basic trust; they lived through a childhood in which significant persons proved un dependable or outright rejecting. It is no wonder that they experience adulthood the same way. The therapist, to such a person, is just another authoritarian figure he expects to be un dependable, hollow, and even covertly malicious. The therapist must, therefore, expect his paranoid patient to be suspicious of anything he says, since all his life the patient has found that significant persons say one thing, usually pleasant and encouraging, but actually do something quite different, usually unpleasant, defeating, and even harmful.

Adults developing paranoid reactions, especially the common persecutory form, almost uniformly consider themselves incapable of loving and being loved. Therefore, the therapist should not expect to be regarded by his patient with anything but dislike and resentment for a long time, during which time he will be secretly tested by the patient. One may well ask at this point why a paranoid person comes voluntarily to a therapist. The answer is not hard to find. The patient usually knows that he is distrustful; he is uncomfortable about it and wants to change, even though he may resist change, just as another patient struggles against the removal of a tooth by a dentist he has asked to remove it. It is painful to suffer from a paranoid reaction, and it is painful to go through the difficult process of overcoming it.

The therapist of a person with a paranoid reaction must be scrupulously honest with him at all times. He must listen with courtesy to the patient's delusions, if they are communicated, and neither indicate that he believes them—since he does not—nor argue with the patient about them nor hold the patient in any less esteem because of them. On the other hand, even though the patient makes himself the center of attention through his pathology, the therapist must avoid too much friendliness or kindness. A friendly but distant neutrality is usually the most that a paranoid person can accept at first without becoming suspicious that he is being submitted to the "old treatment"—first the kindly word and then the acts that demonstrate that all this was a parade to humiliate him and make him feel an unloved, unlovable fool.

The patient's role in good psychotherapy is to say what he wants to say, when he feels safe in saying it, and when he feels the therapist really wants to listen to him. As in all psychotherapy, he should be allowed to follow his own lead, interrupted as little as possible, and spared the curse of too much or too frequent interpretation. A therapist may well feel that he is having a difficult time of it when he treats someone with a paranoid reaction; but he can encourage himself, if he needs encouragement, by realizing how much more difficult is the task of a proud, ill used, and often hostile patient to reveal himself and all his humiliating failings to someone he does not trust and does not even like. If paranoid patient and psychotherapist succeed in establishing a genuine relationship with no delusions or at least with only the echoes of the delusions, it may well be the first genuine adult relationship that the patient has ever made and the beginning of many others that he could not have otherwise achieved.

A patient with a paranoid reaction is usually a very anxious person. If the physician treating him feels that the patient's anxiety is more than he can or should handle, the use of chlorpromazine is indicated as a tranquilizing agent. If the disturbance is mild, oral dosages of 25 to 50 mg. three times daily may be tried for a few days to see if the patient tolerates the drug well and shows no undesirable side effects. If individual tolerance is satisfactory and there are no undesirable side effects, the dosage may be increased to 100 mg. three times daily.

Tranquilizers, such as chlorpromazine, should be administered only under the physician's careful supervision. As soon as chlorpromazine can be dispensed with, this should be done, preferably by first reducing the dosage before eliminating the drug. Tranquilizers can sometimes be useful at the beginning of psychotherapy, but they are not a substitute for it.

Suggested Cross References

For a discussion of the theoretical concepts upon which hypotheses about the dynamics of paranoid reactions are based, see Area C, which deals with current theories of personality and psychopathology. The treatment modalities that were mentioned in this section are further discussed in Area G, on psychiatric treatment.

Chapter 17

Psychotic Disorders. III: Affective Reactions

17.1 MANIC-DEPRESSIVE REACTIONS

ROBERT A. COHEN, M.D., Ph.D.

The manic-depressive reactions are fundamentally severe disorders of mood. Though there may also be marked disturbances of thought and behavior, these should be regarded generally as appropriate to the predominant mood.

The manic patient characteristically displays elation or irritability, pressure of speech, flight of ideas, and increased motor activity. The depressive patient displays the converse: depressed mood, mental and motor retardation, and sometimes feelings of agitation and apprehension. Classified as "manic-depressive reaction, other" are patients with mixtures of the two types previously described, with continuous alternation of the manic and the depressed behavior or with progression to hyperacute (delirious) mania or to depressive stupor.

Reflecting the unsettled state of all nosology in psychiatry, however, is the fact that the diagnosis is not made on the basis of signs and symptoms alone; it also includes a consideration of outcome. Manic-depressive reactions of whatever type have a tendency to remission and recurrence (although a single illness is not rare), and they do not progress to a state of mental deterioration. If the patient's progress does not follow any of these patterns, it can be assumed either that the original diagnosis was incorrect or that a different disorder supervened.

History

Almost alone among the functional disorders, manic-depressive reactions are recognizably described in poetic and medical literature from earliest times to the present day. Homer, Plutarch, Hippocrates, and Aretaeus described both mania and melancholia as vividly and eloquently as any modern observer; they characterized them as related disorders, differentiated them from schizophrenia and from senile disorders,

noted the regularity of remissions and recoveries, described the personality types of those who seemed most likely to develop the disorder and the circumstances that appeared to precipitate the attacks. They suggested reasonable treatment regimens, which included environmental, psychological, physical, and medicinal measures.

Although equally perceptive individual observations continued to be made through the centuries, the knowledge and attitudes of the ancients were essentially lost or suppressed during the Middle Ages. As scientific medicine slowly emerged during the Renaissance, psychiatry was freed from demonology, and physicians rediscovered the phenomena described by Hippocrates, Aristotle, Aretaeus, Asclepiades, Caelius, Aurelianus, Celsus, and Galen. The mentally ill were treated in hospitals, which ultimately became humanistic in outlook and scientific in operation. Psychiatrists were afforded opportunities for systematic and long term observations of large numbers of patients.

Current conceptions and classifications of manic-depressive reactions derive from the work of Kraepelin, whose thinking in this area had been influenced by Falret and Baillarger. Falret studied patients with depression and suicidal impulses for over 30 years; he noted that some of them became elated and then depressed again. In 1854 he published a description of the illness, calling it *la folie circulaire*. Working independently, Baillarger published a report on another series of patients, terming the illness *folie à double forme*. He noted that some of the depressions proceeded to the development of a stupor from which (unlike other stupors) patients did recover. In 1882, Kahlbaum clearly described mania and melancholia not as two types of mental disorder but as stages of the same disease. He named a milder form that ended in recovery cyclothymia and termed the more severe and chronic type *vesania typica circularis*.

Impressed by these studies, Kraepelin, in 1896, proposed the name manic-depressive insanity for this entire group of disorders. In it he specifically included "the whole domain of periodic and circular insanity, simple mania, the greater part of the morbid states

termed melancholia, and also a not inconsiderable number of states termed amentia (confusional or delirious insanity). Lastly, certain slight and slightest colorings of mood, some of them periodic, some of them continuously morbid, which on the one hand are to be regarded as the rudiment of more severe disorders, on the other hand pass over without sharp boundary into the domain of personal predisposition. . . . I have become convinced all these states only represent manifestations of a single morbid process. It is certainly possible that later a series of subordinate forms may be described, or even small groups again entirely separated off. But if this happens, then according to my view those symptoms will certainly not be authoritative which hitherto have usually been placed in the foreground." Every serious student of the field should read Kraepelin's elegant descriptions of his patients and accompany him in the systematic examination of the data that led to his formulations.

Epidemiology

In 1843, Luther Bell, medical director of the McLean Asylum, said, "Every year's experience convinces me that the facts regarding this subject which are capable of being arithmetically noted are of too little moment to be worth recording at all." Thirty years later Isaac Ray stated, "No man can be sure when he speaks of a certain form of insanity that he means by it precisely what everybody else does." In the writer's own early training as a resident at Phipps Clinic, he treated patients under the diagnosis of an affective disorder, hypothymergia in Adolf Meyer's terms. Several months later when he moved to the Sheppard and Enoch Pratt Hospital 7 miles away he treated several of the same patients after their transfer—still displaying the same symptoms and with their clinical states unchanged—under the diagnosis of schizophrenia. In the conceptions current in both institutions at the time, the difference in diagnosis did not imply a corresponding difference in an understanding of the etiology, psychodynamics, treatment, or prognosis.

The situation is better today, and efforts are being made to standardize diagnosis. But even when this is achieved, there may still be a lack of important incidence data. What determines hospitalization or clinic referral is not only the presence of a mental disorder but also the tolerance of the setting in which it develops. Serious psychotic reactions may not be brought to the psychiatrist's attention if the individual is quietly depressed and only moderately retarded.

Even though current data are inadequate, it does appear that the incidence of manic-depressive reactions has decreased markedly in the last 50 years. In 1900, 17 per cent of all admissions to the Boston State Hospital and 37 per cent of admissions to the McLean Hospital were so diagnosed; in 1950 the figures were 8 per cent and 16 per cent, respectively. In 1951, there were 5,240 first admissions of manic-de-

pressives to all state hospitals, 4,376 to private psychiatric hospitals, and 4,962 to general hospitals with psychiatric facilities. In 1963, the figures were 1,648 for the state hospitals, and 1,761 for the private hospitals. Only discharge figures are available for the general hospitals; they show an increase to 6,335. In all classes of hospitals, women outnumber men; the ratio is roughly 3:2 in the state hospitals and 2:1 in the private and general hospitals.

The worldwide incidence of manic-depressive reactions is commonly given as 3 to 4 per 1,000. It is said to be less in Scandinavia and northern Europe, and somewhat higher in southern European countries. The Jews and the Irish are said to have a higher than average incidence and also to recover from a degree of disorder that in others might be considered malignant. As in the United States, women in other parts of the world are afflicted more than men and, in sharp contradistinction to schizophrenia, the upper social classes more than the lower. In Kraepelin's series, 58 per cent of the first attacks occurred between the ages of 20 and 35; 35 per cent between 35 and 60. The manic form of the reaction occurs primarily in younger individuals, the depressed type in the older group. As compared to schizophrenic patients, a larger percentage of manic-depressives are married; and, also unlike schizophrenia, the marital status is not related to prognosis.

It is hoped that epidemiological studies now under way or planned by the World Health Organization and other groups will promote the development of comparable diagnostic criteria and incidence data. On the basis of impressionistic rather than rigorous studies, however, the disorder is said to be relatively rare in some primitive societies. Kraepelin reported that the total incidence figures among the natives of Java were comparable to those in European countries, but the illness was characterized almost exclusively by excitement and confusion; depression was extremely rare. This corresponded to the absence of ideas of sin and of suicidal tendency. Chinese living in Java displayed the usual symptom picture. Carothers made a similar observation in Kenya, but he found a smaller number (only 24 depressed patients in a total hospital group of 1,600), and feelings of guilt and self-abasement were not elicited. During the same 10-year period, 45 of 149 Europeans were diagnosed as manic-depressive. Eaton and Weil studied the relatively homogeneous, highly structured Hutterite colonies in the Dakotas, Montana, Alberta, and Manitoba. They found a relatively low incidence rate and an unusually high recovery rate for all psychoses, but the usual predominance of schizophrenia over manic-depressive reactions was reversed in this society, with the latter occurring four times as frequently.

Etiology

The inconsistencies described in epidemiology are

inevitably magnified and compounded in an examination of etiological studies. Kraepelin's work was hailed as a milestone in the development of medical psychology, as indeed it was. He appeared to have brought order out of chaos and to have demonstrated empirically the strong probability that a number of what had been regarded as separate clinical syndromes were manifestations of the same morbid process.

The problem in etiology revolves about those critical words "the same morbid process." Do these clinical syndromes result from shifts in a single definable psychobiological system? Or is it possible, after all, that this group of varied and assorted reactions have as many dissimilarities as they have features in common? As Kraepelin himself said, "the symptoms which have hitherto been in the foreground [may not] be authoritative." Is it a case of the elephant and the blind men—each describing the limited portion he himself has perceived but no one seeing the animal as a whole? Or do we have a group of manic-depressive reactions as we believe we have a group of schizophrenias, and do concordant studies meant to bring together the different aspects of a single process instead bring to light contrasting aspects of several processes? Although the definitive studies remain to be undertaken, it would be a safe bet that the answer to each of these last questions will be a qualified "yes." The critical question is not "Is it nature or nurture?" but rather "In what ways and to what extent is it nature and in what ways and to what extent nurture?"

Hereditary factors. Investigators who try to assess the contribution of hereditary factors to temperament, character, and mental illness are faced with a most difficult problem. Even dogs can be trained to do an astonishing number of remarkable tricks as well as such useful work as guarding and shepherding a flock or flushing and retrieving a fowl. Here training clearly builds upon an inherited ability. In humans how can one parcel out an inherited trait from those that result from years of training by a manic-depressive parent who is also the natural object for identification?

It does appear true that manic-depressive illness has a higher than average incidence in the parents, siblings, and children of manic-depressive patients. Kraepelin found "taint from the side of the parents" in 36 per cent of his patients; when he considered only those patients who had repeated attacks, the figure rose to 45 per cent. Stenstedt and others give figures of approximately 10 per cent. Perhaps the most persuasive evidence comes from the studies of monozygotic and dizygotic twins. Kallmann assembled his own findings with those of several others and gives an incidence of 20 to 25 per cent in siblings and nonidentical twins, a level much higher than in the general population; while identical twins are found to have incidence figures ranging from 66 to 96 per cent. He believes that the data support the concept of dependence on

the effect of a single dominant gene with incomplete penetrance. Slater and Stenstedt agree with this view, and Rosanoff, attempting to account for a higher incidence of the illness in females, suggested that the gene might be sex-linked.

Just what it is that is inherited is a matter of speculation: Kallmann postulated an alteration in a specific neurohumoral control mechanism, Bellak a specific ego weakness, Abraham a constitutional tendency to increased oral erotism, and Kraepelin an unspecified metabolic abnormality. Interest in this field of research continues; there are a number of studies under way that, building on the foundations laid by earlier workers, are bringing more sophisticated research designs and case findings and evaluative and statistical techniques to bear upon the problem.

Constitutional factors. Folklore has long associated temperament with physique. The jolly fat man is a familiar stereotype; Caesar was not alone in distrusting Cassius with his "lean and hungry look." Kretschmer elevated these notions to a scientific study in 1921 and reported a disproportionately large number of pyknic individuals among those with a cyclothymic personality and specifically with manic-depressive psychosis. Sheldon developed a related but more sophisticated approach in which the individual is described along three dimensions: endomorphy (massive viscera, rounded fatness), mesomorphy (bone, muscle, and connective tissue predominating), and ectomorphy (fragility and delicate linearity of build). Kretschmer's pyknic manic-depressive patients correspond to Sheldon's mixture of high mesomorphy, moderate endomorphy, and relatively low ectomorphy. According to Sheldon's scheme, too, cyclothymic personality patterns have a higher than average representation among individuals with this constellation of somatotype components.

In addition to body build as such, some idea of the vast range of etiological processes that have been advanced may be afforded by merely listing suggested dysfunctions: (1) of the endocrine system, (2) of the diencephalic centers involved in affective expression, and (3) of the processes which in lower animals are involved in hibernation, since the psychosis seems to occur more frequently in the spring.

Biological factors. For over 100 years each new technical advance in the methods of anatomy, histology, physiology, biochemistry, and pharmacology has been brought vigorously to bear upon the problem of the manic-depressive reaction in an effort to identify the structures or the biological processes that may be involved in the disordered behavior. Few of the numerous tentatively positive findings withstood the test of replication.

Recently attention has been directed to the autonomic nervous system, where activity appears to in-

crease in some depressive states when psychological defenses fail and to return to normal when the defenses are reconstituted. In the first studies relatively crude clinical measures were employed, but the rapid development of sophisticated biochemical techniques has brought new information that promises to increase the explanatory power of some biological hypotheses. At the outset, however, it is well to call attention to some of the problems in interpreting the results of these studies.

Psychobiological aspects. Everyone recognizes that mood is a complex psychobiological state and that changes in mood must reflect changes in both physiological and psychological processes. The experience of joy or pain or fear has a psychological and physiological component. Joy as we commonly experience it would not be joy if only the normally occurring psychological or physiological process were active. Just what it would be we may be able to demonstrate experimentally in the not too distant future, since the identification of some of the biochemical systems involved and of suitable blocking agents seems an attainable goal.

Many etiological studies seem at first glance to take the position that the disorder has either psychological or physiological roots. Most investigators would agree, however, that what they have tried to do is to focus on one area in depth in order to gain the maximum amount of information about a part of the total process. It is as if one sees only a spotlighted figure on a darkened stage; the rest of the cast will join in playing out the story, even though, for the moment, they are not seen. A shortcoming in collaboration up to this time is that biologists and psychologists have tended to select different groups for intensive study; hence it is not possible to combine such seemingly reliable data as we have from the two spheres of study. There can be no doubt, however, that neurophysiology, neurochemistry, and pharmacology are opening new avenues to the understanding of behavioral mechanisms.

Antidepressant drugs. The antidepressant drugs have attracted particular interest not only because they favorably affect the course of depressive illness but also because they can be used to explore biochemical mechanisms that may accompany or be responsible for depressed behavior. Attention was called to this problem by the discovery that iproniazid, an effective clinical antidepressant, is also a monoamine oxidase inhibitor, and monoamine oxidase is importantly involved in the metabolism of the brain amines. Animal studies have shown that iproniazid and other monoamine oxidase inhibitors that are clinically effective increase the brain levels of norepinephrine and serotonin and also lead to excited behavior. It was proposed that this might mean that depression was caused or accompanied by a decrease—and elation by an increase—in brain catecholamines.

This hypothesis was strengthened by information

from another source; imipramine, which is among the most effective antidepressants clinically, is not a monoamine oxidase inhibitor. It decreases cell permeability to norepinephrine and thus prevents its inactivation or binding by the cell. The net effect, therefore, is to increase the available concentration of norepinephrine just as the monoamine oxidase inhibitors do by another mechanism. Still another line of evidence is the finding that dihydroxyphenylethylamine (dopamine), which is a precursor of catecholamines, counteracts the effect of reserpine, which in its turn is thought to deplete brain serotonin and norepinephrine. In animals both imipramine and monoamine oxidase inhibitors reverse the sedation brought about by reserpine.

Metabolic aspects. Changes in the metabolism of the adrenal steroids have also been reported in depression; it must be noted, however, that such changes occur in almost any condition of emotional arousal. Although the levels of urinary 17-hydroxycorticosteroids are often found to be normal in cross-sectional studies of depressed patients, Bunney and associates found marked fluctuations when certain patients were followed longitudinally. In this group, high levels appeared to be associated with a breakdown in the defenses against psychic distress but not necessarily with a high degree of manifest anxiety. Three patients who committed suicide were found to have the highest levels of 17-hydroxycorticosteroids recorded in his study; one of these patients also had the highest level of urinary epinephrine and norepinephrine. To the extent that it could be determined, the increases in 17-hydroxycorticosteroids and in psychic distress paralleled each other on the crisis day. In one patient who alternated every 24 hours between a manic hyperactive and a depressed underactive state, Bunney et al. noted that the hydroxycorticosteroid levels were consistently higher on the depressed days.

Some changes in electrolyte, water, and carbohydrate metabolism have also been reported in depressed patients, although most of these studies have not yet been widely replicated. There is suggestive evidence that during an acute depressive attack there may be an impairment of the mechanism that excludes sodium from cells and a decrease in the rate of transfer of sodium from the blood to the cerebrospinal fluid. When electroshock therapy is given, *only those patients who improve clinically show a return to normal.* Another interesting but unexplained finding is the reported very high effectiveness of lithium in the treatment of manic attacks.

A cautionary word is in order concerning all these findings. The drugs that are so effective in bringing about clinical improvement and the mechanisms associated with alterations in catecholamine and 17-hydroxycorticosteroid levels that seem to be associated with the return to normal behavior may be compensating for some other abnormality that has not yet been defined. It is not yet proved that it is the change in the levels of these metabolites that causes the

manic-depressive reaction, or, rather, the depressed reaction, since that is the state that has been most intensively studied.

Psychological and psychodynamic factors. Early writers called attention to the fact that most manic-depressive illnesses occurred in individuals who were constitutionally of a depressive, manic, or cyclothymic temperament; the disease was believed to be simply an extreme swing in the characteristic behavior of these individuals.

Kraepelin's theories. Kraepelin believed that, compared to this innate predisposition, external factors played a subordinate part in the causation of the disorder. It was recognized that a multitude of more or less traumatic events was apparently associated with the precipitation of attacks: death or the severe illness of a loved one, unrequited love, financial losses, purchases, sales, engagements, the attainment of long sought goals, etc. Kraepelin believed that these carefully documented incidents had little or nothing in common and that their very multiplicity spoke against the importance of any single one of them. Even more crucial, in his view, was the fact that the illness might appear to be precipitated by a relatively insignificant event in an individual who had a prior history of withstanding the most serious stress and would have a similar subsequent history. There were many instances in which no precipitating event of any nature could be discovered. These variations and inconsistencies led Kraepelin to discount the importance of psychic causality; "manic-depressive insanity may be to an astonishing degree independent of external influences."

Adolf Meyer reacted strongly against what he termed this "either-or" point of view. Rennie, reviewing 208 manic-depressive illnesses treated at Phipps Clinic, reported that 79 per cent had evidence of disturbing life situations in the immediate dynamics, this judgment being based on the content of their productions during treatment or on their retrospective accounts of the onset of the illness. It is clear that, in discussing these psychological and psychodynamic factors, the investigator is not blessed with universally persuasive, let alone incontrovertible, evidence.

Abraham's theories. Psychoanalysts have attempted to develop a systematic psychological theory of behavior and personality development and have had a special interest in the psychoses. Abraham was the first psychoanalyst to study manic-depressive patients. He drew attention to the fact that in periods of remission they were not normal; that is, in the psychoanalytic sense they had never reached the level of maturity in personality development. He described their personality structure as closely resembling that of obsessive-compulsive individuals. Both personality types display characterological features of egocentricity, intensive ambivalence, and envy; they are gripped so equally by love and hate that they are immobilized in relating to others, being unable to express one emo-

tion without the other. In manic-depressives, the inability to love leads to feelings of inner impoverishment.

In 1911 Abraham explained this clinical picture by utilizing the libido theory of his day. On the basis of the specific transference relationship that developed between the manic-depressive patient and his therapist and on the basis of the patient's recollections of early life experiences, he postulated (1) that these patients have an unusually strong oral drive, which is probably partly constitutional and partly the result of frustrations by and lack of gratifications from the mothering person and (2) that, as a result of his frustrated orality, the individual does not progress smoothly and effectively to the next phase of personality development but relates to other objects with the ambivalent attitude he developed toward his mother (his primary object), being unable to fuse the good satisfying object and the bad frustrating object into an object that is at times gratifying and at times frustrating. This ambivalence is precariously compensated for as the individual matures; he remains unduly vulnerable to frustration by his love objects. When in later life such a disappointment occurs—and any of the psychic causes already listed could be so considered—the patient regresses to his earlier mode of relating to objects; his ambivalent conflict is reactivated and is now directed toward his own ego. The manic attack was seen as a return to and an acting out of infantile freedom, in which the patient gives free rein to his impulses.

Freud's theories. Taking Abraham's hypothesis as a point of departure and pointing out that these findings referred only to those manic-depressive patients whose illness was clearly related to psychological factors, Freud indicated that normal mourning could be considered as a paradigm that might throw light on the nature of melancholia. Where Abraham had emphasized shifts in libidinal cathexes (energy valences or charges), Freud pointed out that clinical observations made it necessary to amplify some of the earlier psychoanalytic ideas about the ego and the id, the structural aspects of personality. Just as the bereaved mourned the loss of the loved one, the melancholic appeared to mourn the loss of his own ego. He suggested that the depressed individual, in withdrawing his libidinal attachment from the lost object, invested it in his own ego rather than in another object. Part of this libidinal energy served to establish an identification of the ego with the abandoned object; the remaining libido under the influence of the ambivalent conflict is reduced to sadism visited upon the ego. This sadism originally would have been directed toward the depriving object with which the ego is now identified.

It was partly in order to account for this process of identification and sadistic attack upon the ego that the structural theory was modified; what had been included in the original concept of ego was divided now

between an ego and an ego-ideal and later between ego and superego. Freud suggested that struggles between the superego and the ego took the place of struggles between the ego and its ambivalently loved object. He believed that the reason the melancholic patient is so often arrogant and demanding instead of ashamed and submissive as he describes his unforgivable sins and utter worthlessness is that these self-reproaches are really directed at the supposedly beloved object.

Object relationship. There have been further elaborations of psychoanalytic thinking about manic-depressive psychosis. Among the most important is that which had originally been considered as a turning away from objects is considered now as an object relationship that has been impaired by regressive alteration in ego and superego functions. This regressive change serves as a defense against the development of disruptive anxiety in conflict situations. In the psychoanalytic literature generally, mania is viewed as a defense against melancholia.

Relationship to life history. Psychoanalytic theory represents an attempt to understand current behavior in the light of the individual's life history. It suggests hypotheses for research in two areas: in psychotherapy and in personality development. Developmental psychological research is rapidly expanding, and in some longitudinal studies now in progress an effort is being made to characterize by objective criteria interactions between infants and parents in ways and at developmental phases suggested by psychoanalytic theory.

In psychoanalytic therapy of manic-depressive patients, interpretations are made on the basis of theory, and presumably it is these interpretations that bring about change in the patient's behavior. It is obviously difficult to evaluate this. In the case of manic-depressives, particularly, the problem is compounded by such observations as Rennie's in the study previously mentioned, in which he found that 93 per cent of the Phipps patients recovered from the first attack. Even though 79 per cent of them had recurrences, it would be impossible to prove that the patient one "cured" would have fallen into that group. A further difficulty is that any one analyst is unlikely to have analyzed more than several manic-depressive patients.

The problem of the validation of psychoanalytic hypotheses remains to be solved but it has attracted the interest and efforts of a number of able investigators. The psychoanalytic scientist would have to be able to state whether the patient's improvement represented a return to his prepsychotic state with no essential personality change, in which case he would presumably be vulnerable to further attack or whether there has been not only a clinical improvement but a degree of maturation with consequent increase in effectiveness of the patient's object relations, in which case it would be assumed that he now had personality

defenses that are less disruptive than the manic-depressive reaction.

Cohen et al. studied in some detail the intensive psychotherapy of 12 manic-depressive patients. They attempted to define the character of the interpersonal relations reported and observed during the treatment and to relate the reported early life history to these characteristics. Their findings were checked by an independent investigator who examined a random selection of case histories of a group of manic-depressive, lower-class patients treated in a state hospital. Certain behavioral characteristics and aspects of early life history were common to both groups of patients.

During periods when the patients in the study were free from psychosis, they displayed behavior generally characteristic of those with a constitutionally depressed temperament. Several had occasional periods of moderate euphoria, and during psychotic episodes some had typical acute manic attacks. They were highly dependent upon the esteem and approval of others and, correlated with this, held values which were both conventional and changeable in conformity with what they perceived to be those of their group. They were unusually competitive and almost childish in their envy of others; the defense of denial was often employed, and associated with this was an insensitivity to the feelings of others and to their own motivations. It was as if these patients had given up any desire to achieve maturity and self-sufficiency, in exchange for approval of the person on whom they were dependent. They endeavored to gain this approval by doing whatever they believed that person wished them to do. At the same time they were envious and competitive, not only with the object of their dependence but with anyone whom that person chanced to notice. Their own pervasive envy of others led them to fear becoming themselves objects of envy by others. Consequently, they also feared success in achieving the dependent aims they persistently sought.

The patients appeared unaware of this conflict and ambivalence. Ostensibly, they appeared to enjoy friendly relations with everyone; those who displayed outgoing trends tended to have numerous, but superficial, relationships. Others were more reserved and concentrated on one or a few important persons. They actively avoided awareness of the broad implications of their own or others' behavior, and early in treatment they were nonpsychological in their thinking. Their productions in therapy had more of a factual than an interpretive quality. Yet they were sufficiently subtle to manipulate their objects to secure gratification of their dependent desires.

Among the common characteristics of the family histories were: (1) isolation of the family from the social environment by some factor such as economic, religious, or racial difference, (2) parental awareness of this difference and extraordinary efforts to maintain or raise family status by strict conformity to accepted values, (3) parental manipulation of the chil-

dren to gain the desired status, with the ultimate effect that the patient came to value himself in proportion to his conformity to these values, (4) continued emphasis in the family on the absolute need for conventional success, with resulting feelings of high competitiveness with and envy of others, (5) in most intensively studied cases, greater aggressiveness, ambition, and rigidity in the mother than in the father, who was often blamed for the sad family state from which the patient was the potential rescuer, and (6) notable inconsistencies in discipline, in which the child was at times punished for behavior that at other times brought no reaction.

Gibson checked these findings in the case histories of 27 manic-depressive and 17 schizophrenic patients who had been treated at a state hospital. Except for parental role reversal and inconsistent and harsh discipline, which occurred with equal frequency in the experimental and two control groups, the characteristics of the manic-depressive patients' behavior and the early life histories were essentially the same in both groups; and these stood out in sharp contrast to the family experiences of the schizophrenic patients. However, in the original study the schizophrenic and his family had been kept in mind as a reference group. More research needs to be done on family interaction patterns in normals, in those with various mental disorders, and in all social classes to determine the precise nature of the contribution such patterns make to an individual's development. The findings in studies that have already been undertaken suggest the importance of specific family experiences in the development of manic-depressive reactions.

Investigators appear to have adduced sufficient evidence to indicate that various factors play some role in the development of the manic-depressive reaction. What is lacking is a way of weighting each factor with accuracy and precision. It seems reasonable to expect that with further research groups of patients can be characterized by certain patterns of factors. This point of view is well described by Bellak in his multiple-factor psychosomatic theory of manic-depressive psychosis.

Clinical Description

The American Psychiatric Association diagnostic classification is based on the concept of manic-depressive insanity proposed by Kraepelin in 1896. In a day when therapy consisted principally of hospitalization, control, support, and moral treatment, there was much to be gained in following his suggestions. It was clear that this group of psychotic patients, whether entirely homogeneous or not, pursued a different course and related to others in quite a different fashion than did the group with the disease labeled dementia praecox.

Adolf Meyer stated that even so perceptive a phenomenologist as Kraepelin found it necessary to change his diagnosis of manic-depressive insanity in an appreciable number of patients after the Wasser-

mann test was instituted as a regular laboratory procedure in his hospital. Today, as we review the results of electroshock and the drug therapies, it appears that among the manic-depressive patients some groups respond differently to these therapeutic agents. A growing body of opinion holds that these differences in response reflect underlying differences in psychopathology or pathophysiology. The patients' behavior patterns are being scrutinized more closely again, and efforts are being made to define certain subgroups within the diagnostic categories, subgroups that respond more or less favorably to one type of treatment but most unfavorably to another.

Syndromes

Manic-depressive reaction, manic type. There are some people who are blessed with unquenchable gaiety and energy. They soon become the center of every group they join. They may be somewhat superficial but are nevertheless alert. They quickly seize on a new idea, develop it energetically, and manipulate people and things in the environment to ensure its acceptance. They are the movers and doers of the world, never seem to doubt themselves, and only redouble their efforts if they are blocked in achieving their desires.

A state of hypomania may arise almost imperceptibly in such individuals, but it is more dramatic when it develops in one whose basic temperament is more on the reserved or quiet side. In hypomania, the qualities of personality listed above become intensified to a level at which they may be regarded as symptoms, but in casual or brief encounter the individual may still appear as one of God's anointed.

There is a classical triad of symptoms: (1) elated but unstable mood, (2) pressure of speech, and (3) increased motor activity. The hypomanic talks easily, winningly, humorously, and he talks and talks and talks—and talks. He is warm, then friendly, and then uninvitedly intimate and unwelcomely personal. He radiates good health: his eyes shine, there is a sheen in his hair, a glow to his skin, a bounce in his stride; one can almost see the elasticity of his muscles. He is constantly on the go and never seems to tire. Only as one stays with him does one become aware of a distractibility; of impatience and intolerance when his wish is not immediately gratified; of impulsive and ill considered actions; of unseemly self-indulgence; and of his bland disregard of patent difficulties.

In acute mania all the foregoing manifestations are more intense and more disturbing to those about the individual. Propriety, convention, discretion are painfully absent. The patient demands and attempts to command the center of the stage. He puns, teases, cracks jokes—some of them good, some awful, some coarse, some blasphemous. His excessive good humor is transformed instantly to the most vicious anger if he is crossed or ignored. He is inconsiderate of others and disregards their needs, comfort, and rights. He is

constantly on the go, moves quickly from one activity to another, never finishes what he starts. His speech is like his movement, with flight of ideas that may proceed to clang associations and actual incoherence. He may burst into tears momentarily when he is faced with some realistic problem, but an instant later he is all smiles and miles away. Every impulse is expressed in words and, unless he is restrained, in action, too.

There is loss of contact with reality, an inability to adhere to a line of thought and pursue it to its logical conclusion and not infrequently what appears to be a delusion of wealth or great power or both. However, these symptoms have a quality quite different from the superficially similar behavior of the schizophrenic. Although the manic has no more control over his behavior than the schizophrenic, one does not feel that he is alienated to the same degree; it seems to be more a case of denial and loss of normal inhibitions without the deep disturbance of the sense of identity. However, the manic patient may not be quite clear with regard to time and place; he may misidentify people and occasionally greet total strangers as friends of long standing. Quite commonly an attack of acute mania starts with a brief period of depression which the family recalls in retrospect but which was not a matter of concern at the time.

Delirious mania is the most intense state of disturbance. It may develop gradually, the patient progressing through the two more minor stages, or it may develop full blown. All of the previously mentioned symptoms may be present, but now in the most extreme form. The patient is totally out of contact, his speech is incoherent, and he is constantly and purposelessly active; he may be incontinent of urine and feces. Hallucinations and delusions are common. It is impossible to develop sustained contact with the patient, and hence one cannot gain his cooperation.

Manic-depressive reaction, depressive type. There are some people who almost always appear somber, quiet, and withdrawn. Somehow one never quite knows what to say to them; they are invariably polite and briefly responsive to overtures, but they never take the lead, and every conversational gambit seems to die. They are good people, sincere and earnest; they are not without compassion but are moved more easily to tears than to laughter. One gains the impression that they are competent and reliable, but they never seek responsibility and most definitely would rather be followers than leaders. John Milton could well have referred to them when he wrote, "They also serve who only stand and wait."

A state of simple retardation may arise almost imperceptibly in such individuals, but it is much more dramatic when it develops in one whose basic temperament is more on the outgoing or energetic side.

In simple retardation the qualities listed above become intensified; there is a classical triad of symptoms: (1) depressed mood, (2) difficulty in thinking, and (3) psychomotor retardation. The patient appears

dejected and cheerless; everything he says and does is with effort. His expression is dull, he is careworn and bent over, his every move is painfully slow. There is no spontaneity. He speaks only in response to questions and even then answers in a word rather than a sentence. One must ask a series of questions to get the most ordinary information: "When were you born?" "July." "July what?" "July 14." "What year?" "1925." He answers as if he were searching for long forgotten memories. He speaks in such a low voice that one finds oneself moving close to him and speaking more loudly, as if he were the one who can't hear. He says that everything is hopeless, that he is a disgrace to his family; he recalls that when he was a boy he took a paper from the newsstand and did not pay for it; he did not finish a task his employer had given him, and he will never be taken back on the job. His appetite is poor. His sleep is restless, and he awakens early each morning feeling worse than he did when he went to bed. He thinks he should end it all, and suicide is a very real danger; he may kill his children, too, to spare them disgrace and the agony of life. There is no disorientation or intellectual defect, however.

There is a variant of this picture, in which the depressive affect and retardation are much less prominent. These patients have multiple and persistent somatic complaints: a constant but vague feeling of malaise, of things being not quite right, headaches, nausea, a feeling of being choked up or stopped up, abdominal discomfort, constipation, weakness, easy fatigue, tension, and restlessness. They continue to work but find it difficult to get things done. They can't read or look at television but find their thoughts turning to their ever present discomfort.

Careful examination reveals no physical basis for the complaints. There may be a history of a similar episode previously for which the patient could get no help but which finally passed off after several months. The patient may give a history of an earlier frank depressive attack or of depressive illness in the family. Here, too, suicide is a danger, which makes it doubly imperative that the patient be recognized as having a depressive illness and not an episode of neurotic hypochondriasis.

Acute depression may follow either of the two states described above, or it may develop suddenly out of the blue. All the symptoms already mentioned are present in more intense form. The patient looks utterly hopeless and deeply dejected. He feels he has committed unforgivable sins, has brought disgrace on the family, and is responsible for every disaster or lesser misfortune that has befallen them. Not only has he been evil in the past, but everything he does now serves only to spread destruction. The family fortune is gone, their home will be taken away, and all is lost. People are disgusted with him, and the newspapers refer to his sinful deeds; the arrangement of the cutlery on his tray conveys a message that he should kill himself. He falls asleep readily but awakens in a few

hours; frightening dreams are common. His appetite is poor; constipation is marked; there is considerable weight loss. He feels that he has no insides, that he is stopped up with feces and other corruption, that he will rot away; that he is foul and disgusting. Suicide is an ever present danger.

Manic-depressive reaction, other. Mixed states are included in this category. In Kraepelin's view these were transitional states, occurring most often as the patient moved in either direction from a manic to a depressive phase but also occurring as interludes in a more or less pure form of mania or depression and rarely occurring as independent attacks. The patient displays a mixture of the signs and symptoms usually present in only one phase of the illness. Kraepelin listed six types of mixed states: depressive or anxious mania, excited (agitated) depression, mania with poverty of thought, manic stupor, depression with flight of ideas, and inhibited mania. The names indicate the principal presenting symptoms.

In alternating or circular states the patient moves from depression to mania and back to depression again without intervening free periods. A complete cycle may occur in as brief a period as 48 hours or as infrequently as once in several months.

In hyperacute delirious mania the severe symptoms of delirious mania are irreversible and death supervenes.

In chronic mania the patient maintains the state of excitement of acute mania for prolonged periods. Cases are on record in which the illness persisted essentially unabated for 35 years.

In depressive stupor depressive signs and symptoms are carried to their nadir. The patient literally does nothing for himself. He lies in bed, does not eat and must be tube-fed, and is incontinent of urine and feces. He responds to nothing in his environment. If an apple is pressed into his hand, he turns it about, apparently not knowing what to do with it or how to get rid of it. Usually mute, he occasionally expresses confused or delusional ideas. After recovery there is little recall of what was felt or experienced in the stuporous state.

Differential Diagnosis

There is no difficulty in establishing the diagnosis of acute mania or acute depression. However, the majority of patients one sees in the office or clinic are not so easily placed in a diagnostic pigeonhole and it is incumbent upon the physician to make a careful longitudinal investigation in which family history, developmental experiences, temperamental characteristics, and the onset and development of the illness, including all behavioral and physical symptoms, are thoroughly reviewed.

Somatic disease. Subclinical or clearly established physical disease may be accompanied by severe depressive symptoms that override the manifestations of the primary process. Depressed mood and apathy or

excitement and irritability may be found in hypertensive cardiovascular disease, uremia, hepatitis, various intracranial lesions—such as general paralysis, cerebral arteriosclerosis, and brain tumor—psychomotor epilepsy, toxic deliriums, drug intoxications, and drug withdrawal states and after infectious diseases. Conversely, the first symptoms of depression may be a variety of somatic complaints so convincingly presented that operations and other heroic somatic treatments have been carried out.

Schizophrenia. This condition may begin with a disorder of mood and, indeed, may continue to present such prominent affective features that the ultimate diagnosis may be schizophrenic reaction, schizoaffective state.

The history will prove helpful. The manic-depressive personality typically has distinct affective features: he usually relates fairly easily to others but in a dependent fashion; he often describes incidents or periods in which there were notable mood swings; feelings of guilt and inadequacy are common; and he shows many of the characterological features of the obsessional neurotic. On the other hand, the schizophrenic has usually been more reserved, remote, and self-contained; his affective responses have appeared to others shallow or even inappropriate; there may have been feelings of strangeness or of bizarre inner alterations; he may report an inner experience of sudden enlightenment in which the incomprehensible became clear to him and he became incomprehensible to others. The schizophrenic illness often starts with a period of panic and dissociation, the manic-depressive attack commonly with a depressive mood swing.

The therapist often feels fairly close rapport with the manic-depressive in his early interviews and only later begins to experience a clinging, wearing, insensitive, limpet-like attachment on the part of the patient that may become quite unpleasant. The schizophrenic patient is more difficult to understand; one may sense a barrier between himself and the patient that cannot be crossed, but for a time at least one may find his sympathy aroused by the obvious distress of the schizophrenic, who, torn by inner conflict, does not make the same type of demand on others that the manic-depressive commonly does.

Psychotic depressive reactions. These reactions are characterized by severely depressed mood, misinterpretation of reality, and, on occasion, delusions and hallucinations. The patients are distinguished from the manic-depressive group primarily by the fact that their illnesses seem to follow immediately upon a clear cut precipitating event. They are usually not given to self-reproach; they blame others or fate and are quite demanding in attitude. Often they can be diverted for brief periods, but then they resume their depressive complaints. These patients are not described as having been of a manic-depressive temperament before the illness.

Involuntional psychotic reactions. These reactions show most of the clinical characteristics of acute depression except that, instead of displaying psychomotor retardation, they are apprehensive, anxious, and agitated. These patients describe themselves as compulsive characters but give no history of mood swings. The illness develops during the involuntional period. Care must be taken to establish the absence of somatic disease, which is common in later life. Rarely does a first true manic-depressive reaction occur in the involuntional period.

Psychoneurotic disorders. These are often accompanied by depressive symptoms, and, conversely, depressive attacks may be accompanied by complaints of neurasthenia, anxiety, or obsessive-compulsive manifestations. Since a depressive attack may culminate in suicide, it is very important to make an accurate diagnosis. Differentiation may be difficult. Neurotic disorders on the whole show a variable and irregular course; the clinical features tend to be changeable and are more responsive to external stimuli; phobias, feelings of depersonalization, anxiety, and apprehensiveness may come and go; feelings of extreme guilt and worthlessness are not commonly present. The neurotic patient is more subjectively than objectively depressed and, although apparently as retarded as the true manic-depressive, is relatively easy to arouse to action. A few studies, not yet adequately confirmed, indicate that the positive biological findings in some psychotic depressions are negative in the neurotic depressions.

Prognosis

Rennie's 1942 study of the 208 manic-depressive patients, who were among the first 1,300 patients admitted to the Phipps Clinic of the Johns Hopkins Hospital between 1913 and 1916, provides one of the more reliable sources of data concerning the course of the illness, since criteria for diagnosis were relatively constant throughout Adolf Meyer's chairmanship. Even so, 99 manic-depressive cases were discarded because the diagnosis was not considered to have been definitely established. Of 17 manic patients, 14 had a second attack, 11 a third attack, 5 a fourth, and 3 a fifth attack. Of 121 depressed patients, 93 had a second attack, 64 a third, 36 a fourth, and 18 five or more attacks. Of cyclothymic patients, only 2 had one attack, 4 had two, 6 had three, and 37 had four or more attacks, one patient having had 20. The average first manic attack lasted $3\frac{1}{2}$ months, the average first depressive attack $6\frac{1}{2}$ months. The shortest first attack was 3 days, the longest 36 months, except for one case of chronic mania which persisted for 24 years. Up to age 45, recurrent attacks are of approximately the same duration; after 45, they grow definitely longer. The manifest depth of the psychosis was apparently unrelated either to the speed or degree of recovery. Eleven of the 208 committed suicide, including two manic patients who had shown no depressive manifes-

tations; 7 others were known to have made serious suicidal attempts.

Treatment

There are two important facts to keep in mind whenever one is asked to see a manic-depressive patient. The first is the ever present danger of suicide, which must always be guarded against, most particularly when the patient is going into or *apparently coming out of* a psychotic episode. The second is that the prognosis for any individual attack is relatively good; hence an attitude of conservative optimism is warranted.

One can be reasonably sure that by the time the patient comes to the physician's office all the common sense remedies will have been tried and found inadequate. Relatives, friends, and employers will have attempted to encourage and stimulate the depressive, will have assured him again and again that he has done no wrong, that they hold him in highest esteem, and that his fears and concerns are without factual basis. They almost certainly will have made him take a few days off and may even have sent him off on a vacation. They will have indulged the manic, will have gone along with his many requests, may even have undertaken certain ventures he suggested, will usually have tried the few days off and vacation gambit, and only recently will have come to suspect that something is wrong, since he has become more rather than less demanding, hyperactive, dissatisfied, and impulsive.

Hospitalization. The first decision to be made is whether the patient can be safely treated at home or should be sent to a hospital. The development of psychiatric units in general hospitals has made this an easier decision than it was when hospitalization necessarily meant a psychiatric hospital with the snake pit images associated with it in the popular mind. If the patient is in a state of acute mania or acute depression, hospitalization is imperative. In simple retardation or hypomania, one may decide whether to try ambulatory treatment on the basis of his evaluation of the situation. The items to be considered are the history, current status, nature of the patient's interpersonal relations, and the patient-doctor relationship.

If there is a history of a previous attack, one can assume that the current illness will be of the same or greater severity and duration. If the patient was hospitalized previously, he should be admitted again for at least a brief period. There is a grave risk that he would interpret a conclusion that he did not require hospital care not as an encouraging finding but as an opinion that he is hopeless and not worth the expense entailed.

It is difficult to decide on hospitalization on the basis of symptoms alone, but if a careful history reveals that the hypomanic has already shown some impairment of judgment in his financial affairs or has

committed serious indiscretions, it is advisable to remove him temporarily from a deteriorating situation. If the depressive has shown continuing weight loss and persistent insomnia with early morning arising; displays deep anxiety and agitation; describes sudden emotional outbursts or gives a history of these supplanted suddenly and recently by an attitude of hopeless resignation; avoids contact with those to whom he previously has been very close, then he may be considering suicide, and hospitalization is necessary. If the relatives, friends, and business associates are too intensely involved with the patient and are bombarding him with advice and suggestions, or, conversely, if one senses that important relationships at home or in the office have been worn thin and that an explosion is likely, a period in the hospital and out of his usual setting would be helpful to the patient and all concerned. If the patient himself sought the referral, it is a good sign. If he came at the insistence of others, it is an indication of a change in their attitude toward him; the meaning of this to the patient must be evaluated (not by direct questioning) to learn whether he believes they consider him hopeless; he may take the fact of the referral as an incentive to suicide.

Finally, even if all the foregoing favored ambulatory care, it should not be undertaken unless the physician feels that a substantial responsive contact has developed between himself and the patient in the course of the examination, no matter what treatment he plans to prescribe. Until this contact is established in the hospital or out of it, the risk of impulsive acting out continues and may increase.

Electroconvulsive therapy. Electroconvulsive therapy (ECT) has been widely used and is regarded as a specific symptomatic treatment for the depressive attack. Usually there is dramatic improvement following one or two treatments, and a course of six or eight, given over a period of 3 or 4 weeks suffices for most patients who respond favorably. It is used less successfully and less often as a treatment for the manic attack. It is generally accepted that ECT is most effective in the treatment of involutional melancholia and endogenous depressions and that it is relatively ineffective or may have an adverse effect in anxiety states. There has been an increasing trend on the part of its adherents to give ECT on an out-patient basis, with care being taken to provide adequate supervision for the confused and amnesic patient.

There are many, including the writer, who, although recognizing the effectiveness of ECT in aborting a depressive attack, believe that it should be used with caution and then only after other therapeutic approaches have been given a trial. In every case it produces transient mental impairment and in rare instances may result in severe memory loss and other defects in intellectual function. Some, but not all, psychotherapists believe that, when the depressed patient finds himself, as if by magic, suddenly relieved

of symptoms, he quickly represses conflicts and actively avoids consideration of the situational and experiential factors that may have played a significant role in the development of his illness. ECT, in their view, tends to increase the resistance to subsequent psychotherapy, even when the ECT is administered by someone other than the psychotherapist. Other somatic treatments do not appear to have this effect. The effectiveness of psychotherapy in preventing recurrence or prolonging remission of depressive attacks is questionable to some but is regarded by others as offering the best hope.

Several investigators have recently reported a new electrical treatment for depression. An electrode is attached to each eyebrow, a third below a knee cap; they are wired to a vest-pocket battery pack, which passes a current of 250 microamperes. The patient so wired can carry on normal activities. It was found that when the direction of the current was positive at the head, there was a distinct tendency for the patient to feel alert and cheerful.

Drug and electrolyte therapy. Iproniazid and other monoamine oxidase inhibitors and, to an even greater extent, imipramine have been found by some investigators to be almost as quickly effective as ECT. Freyhan has pointed out that drug therapy has the additional advantage of maintaining experiential continuity. There is no amnesia or confusion, as there is following ECT; the patient feels that he is cooperating actively in a therapeutic relationship, and a sense of continuity from illness to health is established. The collective experience with drugs has not yet reached a stage that permits uniformly successful prescriptions for specific symptoms. The imipramine type of drugs are generally superior to other antidepressants in the treatment of retarded depressed patients; chlorpromazine is regarded by some to be the drug of choice in manic attacks. In some cases, combinations of drugs seem to be more effective than any single one.

Lithium carbonate has been used since 1949 in the treatment of manic episodes and has been reported to have brought about dramatic improvement in 4 to 10 days. Patients on maintenance therapy have gone for several years without a recurrence. For unexplained reasons, it has been more widely used in Europe than in the United States.

Grinker and his associates undertook a thorough phenomenological study of depressions and correlated their findings with clinical course and response to various treatment modalities. They found one group of patients who complained of feelings of guilt and loss of self-esteem. They were withdrawn, isolated, and apathetic; also, their speech and thinking were slowed. The premorbid personality was compulsive. These patients responded well to ECT, poorly to psychotherapy, and tended to have recurrent attacks. Another group complained of deep discouragement, helplessness, unworthiness, and sinfulness; they were agitated and extremely anxious and made clinging

demands for attention. The premorbid personality was fairly well integrated; the illness seemed to have been precipitated by a traumatic experience. These patients responded well to drugs and psychotherapy. A third group was agitated, demanding, and hypochondriacal and had many psychosomatic complaints. The premorbid personality evaluation elicited a history of lifelong disturbance. Support, reassurance, and drug therapy afforded this group only passing relief; ECT made them worse; a few improved after long term intensive psychotherapy.

Psychotherapy. The efficacy of psychotherapy in the treatment of manic-depressive reactions and in the prevention of future attacks is a matter of controversy. Some psychiatrists feel that there is insufficient data to support the hypothesis that psychotherapy is a useful treatment modality in these conditions; others feel that psychotherapy is of great value.

In the psychotherapy of the manic-depressive reaction, as in other behavioral disorders, the physician may have in mind either of two goals. For the majority of patients, the aim will be to offer support and protection during the attack and then to examine customary patterns of interacting with others with a view toward developing a more effective use of assets and an earlier recognition of those situations that regularly lead to frustration and disappointment. The goal is to help the patient make more effective use of his capacities but not to alter his fundamental personality patterns in any essential way. In some patients in whom psychological factors appear to be importantly involved in the genesis or perpetuation of the illness, the patient and physician may decide upon a far reaching effort to bring about a personality change. The major part of the therapeutic work must be done during a period of remission, but it is desirable to lay the groundwork during the psychotic episode.

The principal problem is that of establishing and maintaining a therapeutic relationship. This is difficult with the depressive because he has detached himself from others, has temporarily lost the capacity to relate to them, and is turned in upon himself. Even when he does begin to relate to the doctor, he expects abandonment and tends repeatedly to lose touch. The manic, on the other hand, is hyperactive and distractible; he does not stop long enough to do more than barely recognize the existence of another person.

The therapist must be active with both depressive and manic patients and the type of activity—support, reassurance, challenge, annoyance, scolding, uncritical acceptance—must be tailored to the immediate situation and to the stage of the developing relationship. During the psychotic episode it is important to vary the length of the interview in accordance with the patient's clinical state at the time. Underactive, retarded patients should be seen relatively briefly so that they are not made to feel that they fall short of an expected standard. Productive depressive and manic patients should be seen regularly for set periods, even though

for long intervals it may seem that nothing they say is new or important. A varied program of activity and rest should be prescribed for both manics and depressives. It is desirable and sometimes possible to bring out the manic patient's underlying depression when one repeatedly points out the inappropriateness of his mood to the serious difficulties he has described.

As the therapeutic relationship develops and the patient improves, the physician will come to be seen as a friendly and powerful supportive figure. In this setting, which provides gratification of some of the patient's dependent wishes, one may review with him his relationships and needs with a view to making common sense alterations in certain poor habit patterns, modifying his compulsiveness, and making more creative use of his assets. This approach implicitly sets up a long term obligation to the patient. With appropriate reinforcement, he preserves an image of the physician as a strong, benevolent authority to whom he may turn in time of need. When a recurrence develops after a patient stops taking his prescribed medication, it is reasonable to surmise that what is unreported and probably not noticed is a disappointment in the doctor on the part of the patient, a feeling that he was subtly rejected, that the physician no longer likes him and has lost interest in him.

In intensive analytic therapy, the developing dependent relationship to the physician is not used to gratify the patient's desire for love. Rather it is pointed out to him as an example of the way in which he builds his self-esteem on the approval of others instead of basing it on the exercise of his own considerable capacity for substantial achievement. The numerous manipulations by which he seeks to gain this approval, and which for the most part he is not aware of, are delineated. Their patterned character is exposed by relating current interactions to a series of similar ones in the past. The patient gradually comes to an understanding of some of the forces that impel him to this repetitious self-belittling behavior. Even when it is successful, this type of treatment may have to be carried through a remission, another psychotic episode, and into another remission before the patient and the physician are able to identify some of the critically important interactions.

17.2 PSYCHOTIC DEPRESSIVE REACTION

PAUL E. HUSTON, M.D.

Definition and History

Psychotic depressive reaction first appeared as an official diagnosis in American psychiatry in 1952. The definition in the American Psychiatric Association's *Diagnostic and Statistical Manual* reads: "These patients are severely depressed and manifest evidence of gross misinterpretation of reality, including, at times, delusions and hallucinations. This reaction differs from a manic depressive reaction, depressed type, principally in (1) absence of history of repeated depressions or of marked cyclothymic mood swings, (2) frequent presence of environmental precipitating factors. This diagnostic category will be used when a 'reactive depression' is of such quality as to place it in the group of psychoses."

Prior to 1952 three diagnoses for depression were used: involuntional melancholia; manic-depressive psychosis, depressive type; and reactive depression. The first two were classified as psychoses, the third as a psychoneurosis.

By 1952 the climate in American psychiatry favored addition of another depressive diagnostic entity. Adolf Meyer, with his emphasis on reaction types, helped set the stage for what he called a "reaction complex . . . qualified by the statement of the etiological or dynamic factors at work." This position affirms the dictates of common sense. When grief, for example, appears to pass over into depression, it is considered a reaction to a personal loss. It is reasonable to conclude that losses—such as financial reverses, demotion, or amputation of a limb—may cause depression. The psychoanalytic movement, with its emphasis on impulses, infantile and childhood experiences, and unconscious forces, highlighted the psychodynamics of depression. Also important in establishing a new depressive category were experiences of psychiatrists in World War II; they found themselves without a nomenclature for psychological reactions to stresses of combat.

Since 1952 the subject of depression has become more complex because of new theories, new treatments, and wider clinical experience with mild and atypical cases. New terms have been employed to qualify the word depression, compounding the complexity. Some of the new terms employed are: endogenous and exogenous depression, anxious and agitated depression, depression of psychotic proportions, masked depression, depressive equivalent, depression as a defense, postpartum depression, obsessional depression, and drug depression. These terms imply many different meanings both in theory and in practice.

Further difficulties arise from the various meanings of the word depression. It can mean blueness, sadness, unhappiness, anxiousness, loneliness, emptiness, discouragement, hopelessness, a sinking feeling, lowered energy level, and tearfulness. Patients use the word for any of these meanings and many others, even without reference to any affective state, and professional workers often do not explain in what sense they employ the word.

It is not surprising that some psychiatrists consider depression a unitary disorder with a variety of manifestations, that some accept the four types found in the diagnostic manual, that others deny the existence of one or more types, such as involuntional depression or psychotic depressive reaction. The problems presented by depression in recent years have lead to several symposia on the subject.

This complex and confusing situation can be clarified by considering what is necessary to establish a clinical syndrome. The clinical picture should have: (1) typical signs and symptoms; (2) onset at a recognizable time with a characteristic course; and (3) a definable outcome, such as recovery or a more or less chronic state. In addition to these three factors, it helps to have adequate knowledge on: (4) epidemiology, that is, the occurrence in certain classes of people by age, sex, race, environment, occupation, etc., and predisposing factors, such as heredity, childhood experiences, and metabolic or neurophysiologic facts; (5) etiology, including precipitating factors and pathology; and (6) treatment.

The better a diagnostic entity meets these requirements, the more certain is the diagnosis and the more specific and effective is the treatment.

Epidemiology

There are no reliable statistics on the prevalence of psychotic depressive reactions, and there are only suggestions as to the incidence of this type of reaction. Indeed, it will be difficult to secure reliable incidence or prevalence figures until there is more knowledge about the parameters of this diagnosis. Cultural, regional, racial, and individual differences attach diverse meanings to possible environmental precipitating factors, such as losses. A person accustomed to making and losing large sums of money gambling in the stock market presumably would not be affected as much by a financial loss as a person whose life savings were wiped away by a stock market crash. If death means that the soul of the deceased has escaped the painful vicissitudes of earthly existence and has gone to a happy hereafter, death of a loved one may be a cause for rejoicing rather than depression. If loss of a fortune means release from the onerous responsibility of managing the fortune, the loss may be an occasion for celebration, not depression.

Since nearly every person must experience at least one catastrophic loss in a lifetime, it might be supposed that psychotic depressive reactions are quite

common, perhaps almost equal to the death rate. Clearly this is not the case. According to the United States Public Health Service Reports for 1963, the number of hospitalized cases of psychotic depressive reaction was 4,979, compared with 3,409 cases of manic-depressive psychosis and 6,264 cases of involuntional psychosis. But because of the prevailing confusion about the concept of depression, these figures are not believed to give valid comparative information on incidence.

Etiology

Hereditary predisposition. It seems reasonable to suppose that a psychic trauma may disturb a genetically determined neurohumeral mechanism regulating mood. It also seems reasonable to believe that the genetic regulator may be made more vulnerable by intrauterine infection, radiation, or brain injury at parturition. Though there appears to be a genetic factor in some cases of manic-depressive psychosis, none is known in psychotic depressive reaction.

Physical states. It also appears possible that physical states may make an individual more vulnerable to psychologic stress. Viral infections, malnutrition, and the use of drugs such as rauwolfia are sometimes associated with the onset of depression.

Environmental precipitating factors. By the diagnostic criteria of the American Psychiatric Association, the sole unique feature of psychotic depressive reaction in the group of depressive psychoses is that of environmental precipitation. What constitutes an environmental precipitating factor? Clinical experience points to severe personal losses. Death of a spouse or close relative is placed high on the list. Other losses assumed as important are loss of love, loss of property, a demotion or other serious loss of status. Yet depression also follows what appear on first report to be trivial losses. For example, a man became deeply depressed and suicidal following the death of his dog. Subsequent study of the case revealed an unhappy marriage. A wife hostile to the patient for years had turned his children against him. His sole affective companion was the dog who greeted him when he came home, went hunting with him, and slept on the floor of his bedroom. Loss of the dog severed the only affective tie with a fantasied ideal marriage and home.

The psychiatrist is not alone in the search for significant events. A depressed patient is prone to review his past life. Most often he settles on something about which he has felt guilty, often a sexual misdeed. Now, he imagines, his sins are "catching up with him." Or he remembers he was unhappy 10 years ago, when he was accused of mistreating his wife by one of her relatives. Was there some truth in the accusation? The patient's relatives are also involved in the search for causes. They may say that the bank failure has been preying on the patient's mind for years. If a single, seemingly significant loss cannot be found, it is said

that many small losses accumulated, and, when the barn burned, depression followed. So the search for losses becomes imaginative and creative.

A man was admitted to the hospital for his fourth depression in 10 years. With the first three, no precipitating cause had been determined, but now he believed that all his depressions were due to a 50-cent error made on an income tax report 20 years before. Listing of causes of depression by some authors discloses astonishing alleged events: dog had ticks, delayed by snow storm, went on vacation, unable to go on vacation, etc. Sometimes the depression follows a promotion. This seems paradoxical, but to make this event consistent with the concept of precipitating loss, it is stated that the patient felt unworthy of the promotion and hence suffered a loss of self-esteem.

Grief. Probably the most significant human loss is death of a close relative. The modern period in the study of grief began with Lindemann's report. This was based on 101 persons: psychoneurotic patients who had lost a relative during the course of treatment, relatives of patients who died in the hospital, bereaved disaster victims and their close relatives, and relatives of members of the armed forces. Lindemann described symptoms of normal grief: sensations of somatic distress; preoccupation with the image of the deceased; guilt feelings in which the bereaved accuses himself of negligence in relation to the deceased; feelings of hostility toward doctors and others, charging them with not properly caring for the deceased prior to his death; and a change in conduct patterns, such as restlessness, inability to organize activities or to carry on customary social pleasantries.

According to Lindemann, normal acute grief lasts 4 to 6 weeks. He also listed several varieties of morbid grief reactions. Delayed grief may come on months or even years after the loss, sometimes on an anniversary date of the death. Distorted grief reactions include overactivity without a sense of loss; acquisition of symptoms of the last illness of the deceased; marked hostility without showing grief; apathy; and behavior destructive of the patient's interests by uncalled for generosity, foolish business deals, and agitated depression. Lindemann's study is relevant here because many of the symptoms found in grief are also seen in depression and also because Lindemann diagnosed depression in only a small fraction of the cases. This raises the possibility that grief is a special reaction and not the cause of depression.

Studies on grief have continued. Parkes found that of 3,245 patients admitted to a psychiatric unit in a 2-year period, 94 developed their illness within 6 months of the death of a spouse or parent. This number was six times greater than the expected bereavement rate in the general population. The incidence of affective disorders comprised 65 per cent of the 94 bereaved patients and 47 per cent of the nonbereaved psychiatric patients; 28 per cent of the bereaved group and 15 per

cent of the nonbereaved group were diagnosed as having a reactive depression (neurotic).

In a second study, Parkes compared a group of bereaved patients with a group of nonpatient widows from a study by Marris and found that the patient group had, in general, similar grief reactions. However, the bereaved patients had more trouble accepting the loss and more frequently had ideas of self-blame. The patients also suffered from atypical grief reactions: abnormal prolongation of the grief, unusually intense grief, hypochondriacal symptoms resembling those suffered by the deceased in his last illness, and panic attacks.

In a third study, Parkes presented a more detailed classification of grief reactions. He defined two broad categories: (1) the stress-specific reactions—typical grief, chronic grief, inhibited grief, and delayed grief; and (2) nonspecific and mixed reactions—any of the above along with psychosomatic reactions, psychoneurotic reactions, affective disorders not resembling grief, or other conditions. Parkes found no case of retarded or psychotic depression in his cases, but there was one case of manic illness.

On the basis of the data reported by Parkes and Lindemann, a new classification, grief reaction, may be appropriate. Their work casts considerable doubt on loss by death, by itself, as a sufficient cause for psychotic depressive reaction, although it appears that loss by death may be an associated factor in some cases.

Advanced age. Another approach to the relationship between loss and depression involved persons whose status has changed in the latter years of life. Levin and Goldfarb have indicated that older people are commonly subject to depression. Busse et al. stated that these depressions occurred about once a month and lasted from less than an hour to a few days, they were associated with feelings of discouragement over the future. These persons were aware of the causes of their unhappy feelings, such as physical suffering or lowered financial, professional, or social status. They had not suffered depressions earlier in their lives. Busse et al. do not believe that these depressions were based on unconscious mechanisms, ambivalent wishes, or attempts to force another person to give evidence of affection.

Other writers have referred to the affective state of the depressed elderly as apathy or disinterest rather than blueness. Still others indicate that psychotic depressions are less common past age 65 and believe that older people are more immune to such depressions. A depressive retirement syndrome has been proposed, the symptoms of which are subjective depression, insomnia, loss of interest, lessened concentration, loss of satisfaction in work, social retreat, hypochondriasis, and gastrointestinal and sexual disturbances. Many writers believe that this depressive reaction in the

elderly is usually a mild syndrome in which neurotic symptoms of earlier life reappear.

Physical illness. Dovenmuehle and Verwoerd reported on 62 patients admitted to a general hospital for serious cardiac disease who were rated for severity of depression. They found that 64 per cent of these patients had episodes of moderate to severe depression lasting from an hour to more than a day. Associated symptoms were lowered self-esteem and anxiety. Both mild and severe cardiac disease provoked severe depression during the first 3 years of illness, but after 3 years mild cardiac conditions did not provoke severe depressions, suggesting that these patients adjusted to their situation. Difficulty in sleeping, reduction in appetite and body weight, and constipation were not prominent in these patients. No patient was noted as psychotic. The authors believe that the response of depressive reaction to physical disease is similar to a grief reaction or an acute situational depression.

Stewart et al. reported a clear association between depression and the awareness of having a serious illness likely to be fatal or seriously disabling in 20 per cent of a group of 30 medically ill patients. Compared to manic-depressive psychosis, the depressed medically ill had fewer depressive symptoms, no suicidal tendencies, and no previous history or family history of depression.

Mutilating surgery. Evidence of a relationship between losses and depressive reactions has appeared in studies of patients who had mutilating surgical operations. Sutherland and Orbach have reported that acute depression can occur in anticipation of surgery. After surgery, depression may occur in relation to the loss of some valued activity. If some substitute activity cannot be found, the depression continues. Postoperative patients may also develop persecutory ideas against their doctors and nurses, severe hypochondriasis, anxiety, and marked dependency. These reactions are stronger if the patient cannot form a satisfactory relationship to medical personnel.

In common types of losses, a certain degree of specificity in the reactions to the loss seems probable. A grief reaction, for example, differs from the response to mutilating surgery. In all these types of losses, there may be an element of depression, commonly of a transitory nature. If the patient must continue to live in the presence of the loss, as in the case of a physical illness or a mutilated body, the depressive feelings tend to persist. A few of the persons suffering these losses may become severely depressed.

Psychological predisposition. An interesting approach to the problem of predisposition has been made through studies of the childhood of adults who have developed depression. Brown's work is typical. He compared 216 depressive patients with 267 general medical and surgical patients who were not depressed; 41 per cent of the depressed group and 19.6 per cent of the controls had lost one parent by the age of 15.

Immediately preceding onset of the adult depression were broken love affairs, loneliness, marital difficulties, death of a spouse or relative, loss of job, and trivial quarrels or rejections. A few cases seemed precipitated by influenza!

Loss of a parent. A study by Beck et al. reported on the relationship of orphanhood and depression in 297 routine admissions to a psychiatric out-patient clinic. Instead of using psychiatric diagnoses, a depression inventory was employed as a criterion of depression; the depth of depression was also judged clinically. The sample was divided into three groups, of approximately equal size, according to the scores on the depression inventory. The results showed that, of 100 patients who had high scores on the inventory, 27 per cent reported the loss of a parent before age 16; of 97 patients with medium scores, 15.5 per cent reported such a loss; and of 100 patients with low depression scores, 12 per cent. In addition, those patients judged as severely depressed clinically had a significantly higher proportion of parental death than those without depression—36 per cent as against 15 per cent. These investigators also arranged their groups by standard nosology. Although the psychotic depressive group had the highest percentage of orphanhood, it was not significantly higher than that for the schizophrenic group.

In another study, Sethi reported that there was a significantly greater occurrence of separation in childhood and separation as an antecedent event in a group of patients with high scores for depression as compared with a group with low scores. Childhood separations were defined as death of parents or siblings, marital separation, hospitalization of parents for 3 or more months, or child away from home for 3 or more months. Antecedent separations, all within 6 months of the onset of depression, were classed as the death of one or more parents; divorce or separation of parents; hospitalization of parents, siblings, or self for 3 months or more; absence of parents or patient from family unit for 3 months or more. Sethi believes that childhood separation produces a vulnerability to depression that can be triggered by separation in adult life.

An association between attempted or successful suicide and homes broken in childhood is suggested by Dorpat et al. They defined a broken home as one in which one or both parents were missing for more than 4 years prior to the subject's 18th birthday. The home may have been broken by death, separation, or divorce; or the subject may have left home because of illness or poverty or to marry or find work. The results showed, in general, that in both the attempted and successful suicide groups the incidence of parental deprivation was far in excess of the rates of childhood deprivation in control groups. Significantly more of the completed suicide group, as compared with the attempted suicide group, lost both parents by death.

Dorpat et al. suggested that the successful suicide group was reacting to irrevocable losses, such as the death of a loved one, and that the attempted suicide group was reacting to a threatened separation and trying to prevent it. The authors believe that an unresolved object loss in childhood leads to an inability to sustain object losses in later life.

Another approach to predisposition in depression is provided by investigators who study the effects of the loss of the mother figure in infancy or childhood on personality development. Bowlby is representative of this approach. Children brought to a residential nursery were observed after separation from the care of the mother, sometimes for protracted periods. Upon return home, reports on the behavior of the child were secured from the parents.

Such children typically showed a predictable sequence of behavior when brought to the nursery: protest, despair, and detachment. The protest was against the separation from the mother. The child despaired that she would ever return. Finally, the child detached himself affectively from the mother and from personnel and other children in the nursery. Bowlby believed that this sequence involved ambivalent feelings toward the mother; the child both wanted her and was angry at her for her desertion.

The child's ambivalence after returning home was shown by clinging to his mother and by acute anxiety and rage whenever she left him. If the child had been away more than 6 months or if he was subjected to repeated separations, the detachment may have reached an advanced stage, and there was danger that the child would never regain affection for his mother.

According to Bowlby, this sequence is characteristic of all forms of mourning. After an unexpected loss, there is protest: the bereaved strives either in actuality or in fantasy to recover the lost object and at the same time reproaches it for deserting him. Hope that she will return alternates with despair that she will not. In time, emotional detachment develops, and gradually the mother's permanent loss is accepted. Bowlby suggests an inherited evolutionary basis for anger and reproach in mourning. This pattern or response occurs with every loss, whether the loss is retrievable or not. Pathological mourning occurs when there is an inability to express overtly these urges to recover and show anger against the lost object. Adults who fail to mourn following a recent loss become detached and affectionless. With them the task of treatment is to recover and relieve the latent longing and anger concerning the mother for desertion during childhood.

Despite the literature showing that the incidence of early loss of a parent is high in adult depressed patients, Bowlby noted that delinquent boys also show a higher incidence of loss by death of a parent. Thus, it does not follow that there is a causal relationship between childhood loss and adult depression. However, Bowlby pointed out that children can suffer other

significant losses, such as rejection or neglect by parents. He cautioned, too, that although the relative incidence of loss is higher in psychiatric patients, the absolute rate is low; hence other factors must be operating to predispose to depression.

Gregory has performed an invaluable service by pointing out possible errors of sampling, inadequate statistical techniques, and logical fallacies found in the literature on predisposition. A recent study by Pitts et al., which attempts to avoid the pitfalls discussed by Gregory, finds no significant differences in parental deprivation in the childhood of groups with the diagnoses of manic-depressive psychosis, schizophrenia, neurosis, alcoholism, personality disorder, and organic brain disease.

Relationship with early love object. Another approach to the problem of predisposition comes from the psychoanalytic study of adults and children. This work has been carefully reviewed and evaluated by Mendelson. In general, analytic writers believe that the certainty of being loved and wanted, with its accompanying sense of security and self-esteem, comes about mainly through fortunate relationships with early love objects. Without this, the infant is repeatedly overwhelmed by feelings of abandonment, loneliness, anxiety, and depression. Such severe deprivation leads to a pathological personality development.

Jacobsen, for example, attributes the predisposition to depression to excessive disappointments before the child has learned to handle his ambivalent feelings toward himself and his love object at a time when his endopsychic representatives of himself and his objects have not been firmly established or clearly differentiated. Klein believes that the infant enters a phase characterized by a complex mixture of feelings of grief and hostility over a feared loss of his love object. He feels guilty and self-reproachful. This is referred to as the depressive position. Infants who fail to pass beyond this position are likely to succumb to a similar set of depressive feelings in adulthood after loss of a love object.

Mendelson does not believe, however, that the analytic literature establishes a correlation between infantile experience and adult depression. The theories have been based on too few cases, much of the analytic information is subject to retrospective falsification, and the word depression is not used consistently from one writer to another. Analytic writers, according to Mendelson, have come to recognize that depression is a complex phenomenon embracing many affective states and probably results from inherited, constitutional, and psychological factors.

Clinical Aspects

Clinically, depression is an affective state of sadness or blueness. In mild degree this usually goes unnoticed by relatives and is felt only slightly by the patient; in severe degree everyone remarks on it, and the patient experiences severe suffering. The affective

complaint is that of sadness, low spirits, blueness, dullness, failure to enjoy life, not caring to participate in activities, loss of interest or zest, and a gloomy outlook.

Physical signs. A depressed patient looks sad. His eyes may be downcast and staring; the corners of his mouth sag. He smiles not at all or only rarely and weakly. He slumps, and his shoulders droop.

Many depressed patients manifest retardation as a prominent sign, responding and moving slowly. The flow of thinking is not so rapid as formerly. Patients complain they cannot concentrate and have trouble making decisions that, once made, are subject to uncertainty. Pronounced retardation makes them seem stuporous. However, other patients do not show retardation. Both retarded and nonretarded patients may exhibit restlessness, irritability, tension, or even marked agitation.

The patient's store of energy is depleted. He cannot get started on his daily tasks, which now seem mountainous. His appetite is reduced or absent, food does not taste right, eating is forced. A good proportion of depressed patients have dryness of the mouth. Curtailed food intake leads to weight loss, at times of considerable proportions. Constipation appears in some patients, infrequently interrupted by short bouts of diarrhea.

Sleep disturbance, considered as almost pathognomonic for depression, appears as early morning awakening. Characteristically, the patient awakens at 2 to 4 A.M. and cannot return to sleep. At this time he feels the bluest and suffers most from a subjective feeling of depression and from depressive ideas. Less often the patient cannot fall asleep or experiences broken sleep.

Diurnal rhythm is common. Upon arising, the patient feels blue, anxious, retarded, but by midafternoon or evening there is partial or complete relief. This phenomenon occurs in mild depressions, in the early stages of a depression that later becomes severe, and in the later stages of recovery from severe depression.

The perception of the external world may be altered in depression. Colored objects appear dull or gray, although the patients can name colors correctly.

Somatic sensations may exist for months prior to development of a severe depression. Mildly depressed patients may complain of nothing but somatic sensations that the physician regards as neurotic. Such somatic sensations are prominent in the head. Headache is one, often with a primary occipital locus. The patient also speaks of heavy or dull feelings, of fullness or bursting sensations, of hazy or dozey feelings in the head. Complaints of blurred vision sometimes lead to the purchase of new glasses. After recovery from depression, the eye complaint may persist for 4 to 8 weeks.

The skin anywhere may be the object of paresthesias, and some patients scratch incessantly because of

severe itching. Circulatory symptoms are noted in depressed patients who are also anxious and tense. These are tachycardia, tightness in the chest, and precordial pain. In such patients, blood pressure is apt to be elevated; it falls following successful treatment.

The genitourinary system shows three types of changes: frequency of urination, diminution or disappearance of sex desire, and, in women, reduction or cessation of menstrual flow. Occasionally an increase in libido appears, related to a strong need for affection.

Involvement of the neuromuscular system includes tremors, muscle twitches, muscular soreness, and shooting pains in the muscles of the face, arms, and legs. These symptoms often localize along the spinal axis and in the back of the neck and the occiput. Associated with muscular complaints are those of fatigue or weakness.

Psychological signs. Depressed patients, especially in severe cases, may have delusions. Although these are most often seen in first depressions in the involutional period, they may occur at any age. In cases of repeated depression, they frequently have the same delusional content. The delusions typically involve ideas of sin or guilt, poverty and unworthiness. They reflect the patient's cultural background and individual conflicts. A religious person may feel that he has committed an undefined, unforgivable sin, for which he is being punished; these patients often seek help from religious authorities.

One woman felt that she had succumbed to temptation by the devil following an illusion in which she perceived a ray of sunlight as a yellow snake. The snake, she believed, had poisoned the well, and she in turn was poisoning her own family by cooking with well water. This made the food taste peculiar. God had deserted her, and there was no possible salvation.

A wealthy man of 39 became depressed and insisted he was on the verge of bankruptcy. He could not spend 5 cents for a cigar; he had to walk home rather than ride the bus; medical attention was too expensive and useless.

With delusions of sin, guilt, poverty, and unworthiness, hopelessness easily develops. The patient may conclude that suicide provides the only solution.

A fair proportion of depressed patients have suicidal thoughts and refer to them by implication. Robins et al. discussed these allusions. The patient may speak of getting his affairs in order, making a will, visiting life-long friends or relatives once again, where he would like to be buried, wishing certain persons happiness in the future, being tired of living. He may give to persons close to him some of his personal effects. Others speak directly of a wish to die or intent to commit suicide.

Paranoid features may appear in the delusions. A 44-year-old depressed single woman accused her dentist of seeking to use her for illicit sexual purposes. Her proof of his duplicity was that, when he drilled on her teeth, she felt unnatural sensations in her vagina. Less florid cases show only simple ideas of reference. People seem to allude to the patient in derogatory terms that confirm his idea of unworthiness.

Hypochondriacal delusions may absorb the patient's whole attention. He has heart disease, cancer, or a brain tumor. In some cases these delusions seem to be associated with or preceded by somatic complaints; in others they are associated with life-long fear of a certain disease.

Hallucinations, quite rare in depression, are almost always auditory and condemnatory.

A depressed mood has widespread effects on a patient. He notes his blue mood, sleep difficulties, reduction in energy, and diurnal rhythm, and he seeks an explanation. He wonders if an earlier illness is recurring. He thinks that he is a victim of the latest epidemic. He fears that some hereditary or familial nervous trait is showing itself. Mental retardation and indecisiveness make him unsure of himself and reduce his self-confidence. He notes in the mirror a change in his appearance and feels that other persons see this. He suspects that people speculate on his changed appearance. Does he have some secret sin or immoral wish? As a consequence, he becomes tense and anxious, perhaps fearful, avoiding people as much as possible and watching his behavior so that he does not make a revealing mistake in word or act. He tries to put up a front and maintain a smiling countenance. All this prepares fertile ground for the growth of ideas of reference and delusions. He comes to view everything pessimistically. Loved ones may desert him, and friends turn against him. He feels completely helpless and lost. Even though he feels he deserves this punishment, he thinks he may somehow make it up to those he has wronged, and then all will be well. Still other patients feel that they would be better if only somebody could help them. Some patients seek excessive proofs of affection, presenting a picture of dependent clinging. Others resent the imagined lack of attention and angrily demand it. Both types may make suicidal gestures in an effort to gain affection.

The foregoing signs and symptoms of depression differ in severity and variety in individual cases. The definition of psychotic depressive reaction requires that they be of severe degree with gross misinterpretation of reality and possibly with delusions and hallucinations. Severity of symptoms and gross misinterpretation of reality, however, do not differentiate psychotic depressive reaction from manic-depressive psychosis, depressive type, or from involutional depression. Psychotic depressive reaction does not have unique clinical symptoms.

Diagnosis

Several technical problems related to the diagnosis of psychotic depressive reaction create difficulties for the clinician. These difficulties include the time interval between the external precipitating event and onset of the depression, mild depressions, depression that gradually become psychotic, and repeated depressions.

Time between a precipitating event and onset of

depression. If a precipitating event precedes the beginning of the depression by only a few weeks, it is easy to think of the event as bearing a causal relationship. As the interval lengthens, however, the relationship between cause and effect becomes tenuous. Sometimes the time interval is not so great as noted by relatives, for the patient was gradually becoming depressed but had not appeared so. Careful questioning of the patient often discloses that with an object loss he felt tense and unhappy, and, as time passed, the depression progressively deepened. Without such evidence, events that occur more than a few weeks before the onset of a depression should not be regarded as causal.

Mild depressions. Many depressions which follow a possible environmental precipitating event never become severe. There is no history of cyclothymic mood, previous depression, or neurosis. Most of these cases are probably not seen by psychiatrists, and the state is simply regarded by the patient or his relatives as "low spirits" or unhappiness due to a loss of property, position, a relative, etc. This type of depression is not listed in the official nomenclature.

Depressions that gradually become psychotic. Some depressions begin acutely and reach severe proportions in a matter of hours or days. Other depressions begin with only one or two symptoms, such as a slight diminution in appetite and a feeling of sluggishness in the morning, then gradually progress to a severe form over a period of weeks or months. A case of rapid onset is justifiably called psychotic. But a case of gradual onset is more apt to be thought of as neurotic in the early stages, especially if there is anxiety with or without somatic complaints.

Repeated depressions. A first depression may follow a severe personal loss, and in a second depression no identifiable stress can be assigned. Or a first depression may have no precipitating factors, but the second does. Since there are two depressions, both cases qualify for manic-depressive psychosis, and the diagnosis has to be changed in the first case when the second depression appears. Does one call the second depression in the second case a psychotic depressive reaction? Unfortunately, detailed studies on the symptoms during the course of untreated psychotic depressive reaction are not available to compare with manic-depressive and involutional depressions. Thus, these issues cannot be resolved. It seems unlikely that adequate studies can be carried out because of the therapeutic enthusiasm generated by antidepressant drugs and electrotherapy.

Is psychotic depressive reaction a clinical entity? It does not have clinical features that clearly separate it from other types of depression. It does not have a typical unique group of symptoms or signs, nor does it have a known characteristic course. By definition, it does not make provision for minor depressive reactions to loss. It tends toward inclusion of any loss as a possible etiological factor. There is no limit on the

time factor between the loss and the psychotic reaction. There are no figures on its prevalence and inadequate figures on incidence. Common life situations associated with highly significant losses—such as death, lowered status in the elderly, curtailed physical and social function in serious illness and after mutilating surgery—do not typically lead to psychotic depressive reactions. These losses more commonly lead to reactions specific for the type of loss. The reactions that have depressive elements are generally transitory or mild, though some are severe and chronic. Severe personal loss, though playing a role in some psychotic depressive reactions, is not the sole etiological factor. Though suggestive of a relationship, the literature on predisposition to psychotic depressive reaction as a result of childhood parental deprivation is inconclusive.

Treatment

Since the concept of psychotic depressive reaction focuses attention on a significant loss, two interesting questions immediately arise. In cases of impending loss, such as the expected death of a close relative, a mutilating surgical operation, or retirement in the near future, can plans for adjustment to the new situation be formulated that would prevent depression? The second question is: What can be done to prevent depression, once a loss has occurred? Can the grief reaction, for example, be treated in a way to prevent it from passing over into a psychotic depression? Do substitute involvements help? With a woman who cannot have children because of a hysterectomy, does adoption of a child, the raising of animals, or participation in community affairs prevent a depression? These topics apparently have not been explored systematically, but they seem worthy of intensive study. Unfortunately, the psychiatrist is not called until depression has developed.

The treatment of psychotic depression is primarily empirical. There are several principles of treatment.

Uncovering unconscious motivations. Attempts to probe into unconscious factors possibly related to depression are apt to make the patient more introspective, anxious, depressed, and perhaps suicidal.

Combating depressive ideas. If the patient has ideas of guilt or unworthiness, the psychiatrist attempts to undermine these by minimizing them or by direct denial. The patient is told that he did not commit the unpardonable sin, harm a certain person by word or act, cause the death of a loved one. It is explained that he has distorted and exaggerated his degree of guilt. If the patient has feelings of hostility for which he blames himself, the importance of these is minimized, rationalized, or denied. At the same time, attempts are made to bolster the patient's feelings of self-esteem by pointing to his achievements and good qualities.

Suicidal ideas and ruminations are a constant concern. Getting these into the open frequently relieves

the patient, who then may feel that the psychiatrist knows and understands the worst. The discussion of suicide includes all the patient's reasons for suicide. Appeals to a patient's ethical or religious beliefs may be helpful, since these beliefs usually hold suicide as the greatest sin. From a patient who has confidence in the psychiatrist, it is possible to secure a promise that he will make no suicidal attempts.

In all these discussions, hope for his recovery is held out to the patient. He will recover no matter how futile the future seems; thousands of patients with the same kind of trouble do recover.

Sometimes a patient feels better about his illness if it is interpreted to him primarily in physical terms. He is told that depression is a disorder affecting the part of the nervous system and glands regulating feelings and that this part is temporarily malfunctioning. To justify this statement, the psychiatrist may cite examples: nervousness in hyperthyroidism, premenstrual tension and blues, menopausal irritability, unaccounted for mood swings, his own diurnal rhythm. It seems surprising to hear patients who have considerable guilt say, "If I could only sleep, or eat, or move my bowels, I would feel better." Here special treatment for these complaints may improve the patient's attitude.

The more severely depressed the patient, the more transitory are the results in combating depressive ideas. Yet these attempts are often very useful in easing the depression until more definitive treatment with antidepressant drugs or electrotherapy has had significant effects or before the patient enters the hospital. These efforts may prevent suicidal attempts.

Daily activities. The patient should be encouraged to continue activities within the limits of his available energy but not beyond, since this makes him feel more depleted and discouraged. Activity diverts him from depressive preoccupations and preserves the routine of normal existence. Depressed patients may feel that others can detect changes in their appearance or behavior; therefore, they withdraw from social contacts. In this instance, social contacts have to be planned, taking into account the patient's sensitivities.

The deeper the depression, the less active the patient, but an emphasis on a customary daily routine is therapeutic. It reinforces the expectation that he will recover. To assess how much work and what kind of work the patient can do, the psychiatrist should know what a typical normal week and day is like for the patient. This knowledge provides a check on the progress of treatment. What time did the patient arise, how long did it take him to dress and to shave, what did he eat for breakfast, what work did he do, whom did he talk to and about what, what changes has he noted in himself since the last visit, what time did he retire, how well did he sleep? Concern for him as a physical being gives comfort. It helps to satisfy his need for affection and builds self-esteem.

To improve the energy level and relieve feelings of

depression where there is diurnal rhythm, the psychiatrist may use sodium Amytal (1.5 to 3 gr.) and amphetamine (5 to 15 mg.) at breakfast and lunch time, if no other antidepressant drug is employed. The amounts of these drugs in DexamyI are appropriate for the average case. For patients with agitation or tension, sodium Amytal alone is often better. For patients without anxiety or tension, an amphetamine alone may be more effective.

A good nutritional status must be maintained. Occasionally, severely depressed patients require spoon feeding, rarely tube feeding. Constipation is preferably treated with a mild laxative, such as mineral oil. An occasional patient requires enemas.

Women concerned about disturbance in menstrual function can be told that, after recovery from the depression, the menses will return. Similar advice may be helpful for those concerned about loss of libido.

Sleep concerns many patients. A warm bath and a glass of milk before retiring reduces tension. Perphenazine or meprobamate accomplishes the same end. Chloral hydrate upon retiring is beneficial. Secobarbital (1 to 3 gr.) used as soon as the patient awakens in the early morning is also helpful. Continued use of sedatives for sleep should be avoided because changes in early morning awakening are very helpful in judging the response to treatment. Since patients are apt to feel the most depressed when they awaken early, they are most suicidal at this time. The patient should know that the psychiatrist understands this. If the patient fears he will act on his suicidal thoughts, he should be instructed to call his psychiatrist to discuss his fear.

Environment. Much can be accomplished by management of the patient's environment. Nurses, occupational and recreational therapists, and other hospital personnel who have contact with the patient should be given instruction in the psychopathology of depression so that they can combat depressive ideas without probing into psychodynamic factors. All these persons should pay attention to the patient's physical needs and assist in keeping him active. Everywhere throughout the hospital the attitude of personnel should be that of an understanding desire to help, with emphasis on the patient's recovery.

With out-patients, relatives should have their roles regarding the patient clarified by giving them information on how depression affects a patient. In general, they should play a supportive, optimistic role. Sometimes relatives fear that they played a part in causing the depression. While a patient is depressed, discussion of interpersonal relationships of patient and relatives may stir up animosities and guilt. A better time to discuss these subjects is after the patient has recovered. Relatives should be instructed to observe those signs and symptoms that are useful in judging the progress of treatment. Relatives also need instruction in what to expect from electrotherapy and how to reassure the patient who has memory loss associated with this treatment.

Hospitalization. Many depressed patients can be treated without hospitalization. The indications for hospital care are severe depression or serious suicidal preoccupations, inability of relatives to give adequate care, a seriously depressed patient not responding to treatment.

Drug therapy. In the experience of some, imipramine has given results comparable to electrotherapy. The dose is up to 300 mg. a day in four equally divided doses; the usual dose averages 150 to 200 mg. a day. Amitriptyline has also been useful, showing, perhaps, slightly better effectiveness than imipramine. Tranylcypromine and the monoamine oxidase inhibitors (nialamide and phenelzine sulfate) are used when the other drugs fail. The effects of imipramine appear in 7 to 10 days and reach a maximal response in 14 to 18 days. The response to amitriptyline is quicker.

How long to maintain a patient on drug therapy can be solved at present only by a gradual reduction in dose. With a patient receiving imipramine for 4 to 6 weeks, the daily dose may be reduced by 50 mg. for 2 weeks while the therapist carefully evaluates the patient's condition. If there are no signs of relapse, the drug may be reduced by another 50 mg. a day for another 2-week period. This process of gradual reduction is followed until the drug is discontinued. If the depression worsens, the dose is increased for a 4- to 6-week period, and the process of reduction is started again. There is no way one can know how long the patient requires a drug. Depressions usually last from 8 to 10 months, but there is so much variability in duration that no definite rule can be stated.

Electrotherapy. A most effective treatment for depression is electrotherapy. Some psychiatrists prefer to use it only in severe cases and in the hospital. It is, however, also effective in mild cases and can, with suitable precautions, be given to out-patients. These precautions are directed primarily toward home management between treatments and concern postshock confusion and memory loss. The technique of unilateral electrotherapy is said to eliminate most postshock confusion and memory loss. Electrotherapy has the great advantage of stopping the depressive attack in 1 to 3 weeks. The average number of treatments is seven to eight, given at the rate of three a week.

From both electrotherapy and imipramine or amitriptyline, one can expect good results in 80 to 85 per cent of patients. The remainder improve more slowly—or fail to respond maximally. Some patients respond to electrotherapy, then after a few weeks relapse, and more courses of treatment may be needed. In the early stage of relapse, one or two electric treatments may abort an attack of depression.

Suggested Cross References

Other depressive disorders are discussed in Sections 32.4 and 17.3 on nonpsychotic cyclic depressions and on involutional psychotic reactions, respectively; Section 17.1 on the manic-depressive reaction; and Section

24.2 on the neurotic depressive reactions. Suicide is discussed in detail in Section 33.1, and maternal deprivation in Section 44.1. A discussion on the biochemistry of depression may be found in Section 2.3 in Area B, on the basic behavioral sciences. Two of the treatment modalities discussed in this section, antidepressant drugs and electroconvulsive therapy, are discussed in Sections 35.2 and 35.5, respectively, in Area G, on psychiatric treatment.

17.3 INVOLUTIONAL PSYCHOTIC REACTION

HAMILTON FORD, M.D.

History and Definition

The evolution of the current term "involutional psychotic reaction" to replace the original terminology of "involutional melancholia" is a classic example of the difficulty involved in the nosology of psychiatric disorders. Specifically, this difficulty is incurred in classifying the group of depressive reactions on the basis of their kindred causation, psychopathology, symptoms, and course of illness.

As early as 400 B.C., Hippocrates conveyed status to the word "melancholia" by describing it as a clinical syndrome. The disease received attention from other physicians during the succeeding centuries, but Esquirol, early in the 19th century, became the first physician to give an accurate description of the depressive reaction.

Kraepelin was the first psychiatrist to separate involutional melancholia from the periodic forms of melancholia. In 1896, he described an entity beginning after menopause in women and during late middle age in men that is not a phase of some other type of insanity. This entity encompassed all those gradually developing morbid conditions with anxious depression, apprehension, and the ultimate occurrence of delusions. Further, Kraepelin identified manic-depressive insanity as being constitutional in origin, but he thought that involutional melancholia had an acquired cause.

This diagnostic entity was challenged by Dreyfus, a pupil of Kraepelin, who studied cases of his own and reviewed many of the case histories reported by Kraepelin. Dreyfus decided that melancholia was an adulterate form of manic-depressive reaction and, therefore, not entitled to a separate classification. The German school of psychiatry agreed with Dreyfus, and even Kraepelin came to modify his original posi-

tion. But the majority of English and American psychiatrists reacted adversely and have adhered to Kraepelin's original thesis that a first episode of mental illness occurring in the involutional period and characterized by depression, agitation, feelings of unreality, and somatic and nihilistic delusions does constitute a psychopathological entity.

Around the turn of the century, scientific thought began to move toward devising a workable, nosological grouping of depressive reactions. Adolf Meyer was an exponent of this effort but was doubtful as to the possibility of ever developing a strict classification. Meyer believed that depressive types could be distinguished by their common etiology, symptom complex, course of illness, and eventual results. He proposed to classify all psychiatric disorders under three major groups and placed all forms of depression, paranoiac conditions, exhaustive infectious types, and dementia praecox under the category "symptomatic prognostic groups with complex etiology." Seven types of depression were listed in this group. Meyer advocated use of the term "depression" and the elimination of the word "melancholia," which Kraepelin was then applying to midlife depressions. Meyer recognized a typical form of depression belonging to the period of involution that he termed "agitated depression" or "anxiety psychosis." He differentiated this from the nonagitated depression as marked by retardation with subjective feelings of inadequacy and preceded by mania.
